Photographic Determinations of Stellar Positions.—Dr. B. A. Gould, in a paper presented at the Buffalo meeting of the American Association for the Advancement of Science on August 20, 1886, gives some interesting particulars with regard to his photographic work at Cordova. He states that no northern stars were photographed there except the Pleiades and the Præsepe. On the Pleiades plates all but one of Bessel's stars are found, which fall within the limits of the field; the missing one being of the magnitude 9½, whilst there are depicted on the plates other stars of the magnitudes 10, 10½, and 11. About seventy southern clusters have been repeatedly photographed at Cordova, also more than a hundred double stars, whilst the total number of photographs which Dr. Gould has on hand for measurement is about 1300, only a few having been preserved in which the images are not circular. In addition to these classes of objects, special attention was given for many years to taking frequent impressions, at the proper seasons, of four stars selected, on account of their large proper motions, as likely to manifest appreciable annual parallax. All but one of these four stars—β Hydri—have been included in the lists observed and discussed by Drs. Gill and Elkin at the Cape. Still, it will be a matter of much interest to apply the photographic method of investigation to the same problem, even if for no other purpose than a comparison of the results of the two methods. With regard to the progress made in the measurement of the Cordova photographs, Dr. Gould states that the measurements thus far completed are those of the double stars, the four stars with large proper motion, the Pleiades, the Præsepe, and the clusters Lacaille 4375 and κ Crucis. The corresponding computations have been made as yet only for a portion of the Pleiades plates, but it is expected that all these will be completed at a comparatively early date. The results deduced from the Pleiades photographs will be looked for with much interest, especially as Dr. Elkin has recently executed at Yale College a heliometric triangulation of the principal stars of the group, and the comparison of the results will be a severe test of the photographic method for the determination of stellar positions. But astronomers expect good work from Dr. Gould, and they are not likely to be disappointed. Dr. Gould's paper is published in the *Scientific American Supplement*, No. 556.

Gore's Nova Orionis.—Rev. T. E. Espin announces in *Circular* No. 9 of the Liverpool Astronomical Society that, observing on the night of September 14, he found the *Nova* to have a magnitude of 9·2. The star, he says, appeared very red. The small comes *f* was estimated as of 9·7 magnitude.

Heliometric Observations of the Pleiades.—We learn from *Science*, vol. viii. No. 187, that at the recent meeting of the American Association Dr. Elkin communicated a paper upon a comparison of the places of the Pleiades as determined by the Königsberg and Yale College heliometers. The results given were provisional, but they show unquestioned change of position with reference to η Tauri since 1860. Most of the brighter stars of the group, as shown by Newcomb in his "Catalogue of Standard Stars," go with η Tauri, but among the smaller stars there are unquestioned departures from this community of proper motion.

Gould's "Astronomical Journal."—Our readers will be glad to learn that there is a prospect of the publication of this valuable periodical being resumed. The American Association at the recent meeting passed a unanimous resolution congratulating Dr. Gould on the proposed revival of the *Journal*, and expressing its best wishes for his success.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1886 SEPTEMBER 26—OCTOBER 2

(For the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on September 26

Sun rises, 5h. 54m.; souths, 11h. 51m. 17·4s.; sets, 17h. 48m.; decl. on meridian, 1° 19′ S.: Sidereal Time at Sunset, 18h. 10m.

Moon (New on September 27) rises, 3h. 42m.; souths, 10h. 37m.; sets, 17h. 19m.; decl. on meridian, 7° 12′ N.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′

THE BRITISH ASSOCIATION

SECTION G

MECHANICAL SCIENCE

Opening Address by Sir James N. Douglass, M.Inst.C.E., President of the Section

. . . I propose to address you on a subject with which I have been practically connected for nearly half a century, that is, the development of lighthouses, light-vessels, buoys, and beacons, together with their mechanical and optical apparatus. . . .

During the last century a very considerable increase has occurred in the number of lighthouses and light-vessels on the various coasts of the world, which have been required to meet the rapid growth of commerce. Only during the last twenty-five years can accurate statistical information be obtained, and it is found that in the year 1860 the total number of coast lights throughout the world did not exceed 1800, whereas the present number is not much less than 4000. . . .

Concurrently with the enormous increase in the number of coast lights during the last fifty years, very great improvements have been effected from time to time in their efficiency. In 1759 Smeaton's lighthouse on the Eddystone was illuminated by 24 tallow candles, weighing ⅖ lb. each. The intensity of the light of each candle, I find, from experiments made with similar candles prepared for the purpose, to have been about 2·8 candle units each; thus the aggregate intensity of radiant light from the 24 candles was only about 67 candle units. No optical apparatus, moreover, was used for condensing the radiant light of the candles, and directing it to the surface of the sea. The con-

sumption of tallow was about 3·4 lbs. per hour; therefore, the cost of the light per hour, at the current price of tallow candles, would be about 1*s.* 6¾*d.*, sufficient to provide a mineral oil light, at the focus of a modern optical apparatus, to produce for the service of the mariner a beam of about 2400 times the above-mentioned intensity.

The introduction of catoptric apparatus for lighthouse illumination appears to have been first made at Liverpool, about 1763, and was the suggestion of William Hutchinson, a master mariner of that port. The invention by Argand, in 1782, of the cylindrical wick lamp, provided a more efficient focal luminary than the flat wick lamp previously employed, and was soon generally adopted, for both fixed and revolving lights. In 1825 the French lighthouse authorities effected another very important improvement in lighthouse illumination by the introduction of the dioptric system of Fresnel in conjunction with the improvements of Arago and Fresnel on the Argand lamp, by the addition of a second, third, and fourth concentric wick.

Coal and wood fires, followed by tallow candles and oil, have been referred to as the early lighthouse illuminants. In 1827 coal gas was introduced at the Troon Lighthouse, Ayrshire, and in 1847 at the Hartlepool Lighthouse, Durham, the latter for the first time in combination with a first-order Fresnel apparatus. The slow progress made with coal gas in lighthouses, except for small harbour lights, where the gas could be obtained in their vicinity, was chiefly due to the great cost incurred in the manufacture of so small a quantity as that required and at an isolated station. In 1839 experiments were made at the Orford Low Lighthouse, Suffolk, with the Bude light of the late Mr. Goldsworthy Gurney. This light was produced by throwing oxygen gas into the middle of a flame derived from the combustion of fatty oils. The flame was of the dimensions of that of the Fresnel four-wick concentric burner. An increased intensity over that of the flame of the large oil burner was obtained, but it was not found to be sufficient to justify the increased cost incurred. In 1857 a trial was made by the Trinity House, at Blackwall, under the advice of Faraday, with one of Holmes's direct current magneto-electric machines for producing the electric arc light for a lighthouse luminary, and the experiment was found to be so full of promise for the future that a practical trial was made during the following year.

At the South Foreland High Lighthouse, on December 8, 1858, the first important application of the electric arc light, as a rival to oil and gas for coast lighting, was made with a pair of Holmes's machines, and thus were steel magnets made to serve not only, as in the mariner's compass, to guide him on his path, but also to warn him of danger. In 1859 the experimental trials at the South Foreland were discontinued, but they were sufficiently encouraging to lead to the permanent installation of the electric light at Dungeness Lighthouse in 1862. In 1863 the electric arc light was adopted by the French lighthouse authorities at Cape La Hève.

In 1871, after practical trials with a new alternating current machine of Holmes, two of such machines were supplied to a new lighthouse on Souter Point, coast of Durham, and in the following year the electric arc light, with these machines, was established in both the High and Low Lighthouses at the South Foreland, where it still shines successfully. The early experience with the electric light at Dungeness was far from encouraging. Frequent extinctions of the light occurred from various causes connected with the machinery and apparatus, and the oil light had, at such times, to be substituted. As no advantage can counterbalance the want of certainty in signals for the guidance of the mariner, no further step in the development of the electric light was taken by the Trinity House until the latter part of 1866, when favourable reports were received from the French lighthouse authorities of the working of the Alliance Company's system at the two lighthouses of Cape La Hève. Complaints were also received from mariners, in the locality of Dungeness, of the dazzling effect on the eyes when navigating, as they are there frequently required to do, close inshore, thus being prevented from rightly judging their distance from this low and dangerous point. Therefore, in 1874, the electric light was removed from Dungeness, and a powerful oil light substituted. In 1877 the electric arc light was installed at the Lizard Lighthouses on the south coast of Cornwall, and arrangements are now being made for establishing it at St. Catherine's Lighthouse, Isle of Wight, and at the High Tower, on the Isle of May, Firth of Forth. I have mentioned that the first machines of Holmes at the South Foreland were direct current, the machines provided by him for Dungeness being also of the same type. The French lighthouse authorities, however, adopted for their lighthouses at Cape La Hève the "Alliance" alternating current magneto-electric machines, and, in consequence of the less wear and tear of these machines with greater reliability through their having no commutator, Holmes was required to supply alternating current machines for Souter Point and the South Foreland. Those machines have been running at these stations fourteen years and fifteen years respectively. They have during this period required only a very trifling amount of repair, and are still in excellent order, but the time must soon arrive for replacing them by more powerful machines.

In 1876 a series of trials was made by the Trinity House at the South Foreland, with various dynamo-electric machines, for the purpose of ascertaining the then most suitable machine for adoption at the Lizard. The results were decidedly in favour of the Siemens direct current machine, and machines of this type were accordingly installed at the Lizard Station in 1878. In consequence of irregularities in their working, and because, at the time, Baron de Méritens, of Paris, had perfected a very powerful alternating current machine, it was resolved to send one of the latter machines to the Lizard for trial, where it has worked most satisfactorily for several years. The experience gained at the Lizard suggested that, for the St. Catherine's Station, where it had been resolved to adopt the electric arc light, the De Méritens machines should be employed, and they were accordingly ordered; but, as arrangements were then being made for experiments at the South Foreland for testing the relative merits of electricity, gas, and oil as lighthouse illuminants, it was determined that these machines should first be sent there for the experiments. In 1862 a practical trial was made by the Trinity House at the South Foreland of the Drummond or lime light, but the results were not so satisfactory, after experience with the electric arc light, as to encourage its adoption. In the meantime the successful development of the electric arc light for lighthouse illumination very soon acted as a keen stimulus to inventors of burners for producing gas and oil luminaries for the purpose; in 1865 the attention of lighthouse authorities was directed to the gas system of Mr. John R. Wigham, of Dublin, which system was tried in that year by the Commissioners of Irish Lights at the Howth Bailey Lighthouse, near Dublin, and in 1878 he introduced at the Galley Head Lighthouse, county Cork, his system of superposed gas burners. At this lighthouse four of his large gas burners and four tiers of first-order annular lenses, eight in each tier, were adopted. By successive lowering and raising of the gas flame at the focus of each tier of lenses, he had previously produced the first group flashing distinction. This light shows, at periods of one minute, from ordinary annular lenses, instead of the usual long flash, a group of short flashes, varying in number between six and seven. The uncertainty, however, in the number of flashes contained in each group is found to be an objection to the optical arrangement here adopted. In the meantime the attention of the Trinity House, the Commissioners of Northern Lights, and the French lighthouse authorities was being directed to the question of substituting mineral oil for colza as a lighthouse illuminant. In 1861 experiments were made by the Trinity House for the purpose of determining the efficiency and economy of mineral oils in relation to colza for lighthouse illumination; but, owing to the imperfectly-refined oil then obtainable and its high price, the results were not found to be quite so satisfactory as to justify a change from colza oil, at that time generally used. In 1869 the price of mineral oil, of good illuminating quality and safe flashing-point, having been reduced to about one-half the price of colza, the Trinity House determined to make a further series of experiments, when it was ascertained that, with a few simple modifications, the existing burners were rendered very efficient for the purpose, and a change from colza to mineral oil was commenced. It was found, during these experiments, that the improved combustion effected in the colza burners, in their adaptation for consuming mineral oils, had the effect of increasing their mean efficiency, when burning colza, 45¾ per cent. A further advance was made during these experiments by increasing the number of wicks of the first-order burner from four to six, more than doubling the intensity of the light, while effecting an improved compactness of the luminary per unit of focal area of 70 per cent.

With coal fires no distinctive characters were possible beyond the costly ones of double or triple lighthouses. There are at present not less than 86 distinctive characters in use throughout

the lighthouses and light-vessels of the world; and, as their numbers increase, so does the necessity for giving a more clearly distinctive character to each light over certain definite ranges of coast. This important question of affording to each light complete distinctive individuality is receiving the attention of lighthouse authorities at home and abroad, and it is hoped that greater uniformity and consequent benefit to the mariner will be the result.

During the old days of sailing-vessels, when the duration of voyages was so uncertain, sound-signals, as aids to the mariner, were but little demanded. The seaman on approaching the coast in fog trusted entirely to his lead, and, when he found circumstances favourable for doing so, he anchored his vessel until the atmosphere cleared. But, since the application of steam to navigation, with keener competition in trade, these conditions have been entirely changed. The modern steam-vessel is expected to keep time with nearly the same degree of precision as a railway train, and it is evident that, even with the utmost care and attention on the part of her commander, this requirement cannot possibly be fulfilled, and collisions and strandings must occur, unless efficient sound-signals for fog be carried by each vessel, and powerful signals of this class be provided at lighthouse and light-vessel stations.

These circumstances have led to a rapid development of fog-signals, both ashore and afloat, there being now about 700 of these signals, of various descriptions, on the coasts of the world. We therefore find, as might have been naturally expected, that coast fog-signals have been made, by lighthouse authorities, the subject of careful experiment and scientific research; but, unfortunately, the practical results thus far have not been so satisfactory as could be desired, owing (1) to the very short range of the most powerful of these signals under occasional unfavourable conditions of the atmosphere during fog; and (2) to the present want of a reliable test for enabling the mariner to determine at any time how far the atmospheric conditions are against him in listening for the anxiously expected signal. In 1854 some experiments on different means of producing sounds for coast fog-signals were made by the engineers of the French lighthouse department, and in 1861-62 MM. Le Gros and Saint-Ange Allard, of the Corps des Ponts et Chaussées, conducted a series of experiments upon the sound of bells and the various methods of striking them.

In 1863-64 a Committee of the Elder Brethren of the Trinity House made some experiments at Dungeness upon various fog-signals. In June 1863 a Committee of the British Association memorialised the then President of the Board of Trade, with the view of inducing him to institute a series of experiments upon fog-signals. The memorial, after briefly setting forth a statement of the nature and importance of the subject, described what was then known respecting it, and several suggestions were made as to the nature of the experiments recommended. The proposal does not appear to have been favourably entertained by the authorities to whom it was referred, and the experiments were not carried out.

In 1864 a series of experiments was undertaken by a Commission appointed by the Lighthouse Board of the United States, to determine the relative powers of various fog-signals which were brought to the notice of the Board.

In 1872 a Committee of the Trinity House visited the United States and Canada, with the object of ascertaining the actual efficiency of various fog-signals then in operation on the North American continent, about which very favourable reports had reached this country. Among other instruments, they witnessed the performance of a Siren apparatus, patented by Messrs. A. and F. Brown, of New York. One of these instruments was, in 1873, very kindly sent to the Trinity House by the United States authorities, and tested with other instruments in the experimental trials at the South Foreland in 1873-74. This investigation was carried out at the South Foreland by the Trinity House, with the object of obtaining some definite knowledge as to the relative merits of different sound-producing instruments, and also of ascertaining how the propagation of sound was affected by meteorological phenomena. These experiments were extended over a lengthened period, in all conditions of weather; and the well-known scientific and practical results obtained, together with the ascertained relative merits of sound-producing instruments for the service of the mariner, are of the highest scientific interest and practical importance.

The investigation at the South Foreland was followed up by the Trinity House by further experiments, in which they were assisted by the authorities at Woolwich, with guns of various forms, weight of charges, and descriptions of gunpowder. The powders tested were (1) fine grain, (2) larger grain, (3) rifle large grain, and (4) pebble. The result placed the powders exactly in the order above stated; the fine grain, or most rapidly burning powder, gave indisputably the loudest sound, while the report of the slowly-burning pebble powder was the weakest of them all. Experiments were also made with the object of ascertaining the relative value of the sound produced by the explosion of varying quantities of gun-cotton. Here again the greater value of increased rapidity of combustion in producing sound was clearly demonstrated. It was found that charges of gun-cotton yielded reports louder at all ranges than equal charges of gunpowder, and further experiments proved that the explosion of half a pound of gun-cotton gave a result at least equal to that produced by 3 lb. of the best gunpowder. These results led the Trinity House to adopt this explosive as a fog-signal for isolated stations on rocks or shoals where previously, from want of space, nothing better than a bell could be applied. It is also applied with success to light-vessels. But, wherever the Siren can be installed, it is found to be the most efficient fog-signal yet known, chiefly in consequence of the prolongation that can be given to its blasts, and the ease with which it can be applied, with any amount of motive-power available, to the production of any desired combination of high and low notes for distinctions corresponding with those of white and red, or short and long, flashes of light, and thus affording the required individuality of each station. The experience, however, with the most powerful fog-signal is not at present to be considered altogether satisfactory. With Siren blasts absorbing about 150 H.P., or nearly 5,000,000 foot-pounds, per minute during the time they are sounding, the signal is occasionally not heard, under some conditions of fog and wind, beyond 1 mile, while at other times it is distinctly heard above 10 miles. . . .

In 1881 it was considered by the lighthouse authorities of this country that the time had arrived when it was absolutely necessary that an exhaustive series of experimental trials should be made, on a practical scale, for the exact determination of the relative merits (both as regards efficiency and economy) of the three lighthouse illuminants, electricity, gas, and mineral oil, which, by the process of natural selection, may be regarded as the fittest of all those at present known to science. After many unforeseen difficulties had been overcome, this question of universal importance was, in July 1883, referred by the Board of Trade to the Trinity House, who accepted the responsibility of carrying out the investigation.

A Committee was formed of members of the Corporation, who secured the friendly co-operation of the Scotch and Irish Lighthouse Boards, and many distinguished scientific men at home and abroad. I had the honour of acting, in my official capacity as Engineer-in-Chief to the Trinity House, in making the arrangements for exhibiting the experimental lights, and in reporting to the Board from time to time, as in all other matters referred to me professionally.

These investigations were carried out in full view of all who were in any way interested in the subject. The whole arrangements were open to public inspection, and, in their desire to arrive at a wise and just decision on so important a question, the Trinity House Committee courted the fullest inquiry. Many members of scientific Societies, especially those connected with engineering, were invited, and visited the station. The French lighthouse authorities, who rendered much kind assistance in obtaining observations, sent their representatives to view the arrangements, and officers from the lighthouse services of Germany, Denmark, Norway and Sweden, Russia, Italy, Spain, Brazil, the United States, and Canada visited the station and witnessed the experiments.

In order to obtain, with uniformity and method, a consensus of comparative eye-measurements—in addition to the measurements of the Committee and their officers at their different stations ashore and afloat, to those of the coastguard men at nine stations between Dungeness and the North Foreland, and to the more precise scientific measurements of the experts—special observation-books were prepared, and widely distributed to shipping associations and port authorities, with a view to their securing the co-operation of masters of vessels, pilots, and others navigating in the vicinity of the South Foreland.

The South Foreland Station is especially adapted for lighthouse experiments generally, because of the existing facilities for observations on land and sea. The land in the neighbour-

hood has no hedges and few trees, and affords facilities for observations at distances of between 2 and 3 miles. The station is provided with surplus steam power for driving experimental machines for electric lights, and it is easily accessible from London.

Three rough timber towers of sufficient strength to withstand, without tremor, the effects of heavy gales were erected at the rear of the High Lighthouse, 150 feet apart. These towers were marked in large letters, A, B, and C. A tower was devoted to electricity, B to the gas system of Mr. Wigham, and C to such gas or oil lamps as might be proposed to, and approved by, the Committee for trial during the experiments. A lantern of the usual first-order dimensions, but with an additional height in the glazing for the passage of beams from superposed optical apparatus of the first order, was provided for each tower. The optical apparatus in each lantern was, in the outset, special in relation to the illuminant to be used for producing fixed and flashing lights. For the electric arc lights, optical apparatus of the second order of Fresnel was adopted, the apparatus having a focal distance of 700 mm. The dimensions of this apparatus are greater than optically required for the largest electric arc light yet tried for lighthouse illumination, but the internal capacity is found to be only just sufficient for the perfect manipulation of the light by a light-keeper of possibly robust build. For the large gas and oil flames in the A and C lanterns the apparatus adopted was of the usual first-order size, having a focal distance of 920 mm.

The lanterns were partially glazed on opposite sides, north and south, the southern arc being chiefly for observation from the sea. To the northward the land is better adapted for observations on shore, and here three observing-huts were erected at the respective distances of 2144, 6200, and 12,973 feet; each hut was provided with accommodation for two watchers, and a chamber fitted with a large plate-glass window in the direction of the experimental lights, and special apparatus for their photometric measurement. The third hut proved to be practically of but little value for photometry, the distance being too great; it, however, afforded an accurately known distance for eye-measurements, and a barrack and starting-point for watchers endeavouring to determine the vanishing distance of each light during hazy weather. In this they were further assisted by white painted posts, placed throughout the whole track to the experimental lighthouses, at distances of 100 feet apart, the distance of each post from the lights being plainly marked on it in black figures. For the more exact examination and measurements of the intensity of each luminary and that of the beam from each optical apparatus, a photometric gallery was erected in a convenient position, 380 feet long by 8 feet wide, and provided with all the necessary appliances.

During a period of over twelve months the experimental lights were exhibited, and watched by numerous observers, trained and untrained, scientific and practical. During that period a vast amount of valuable evidence was collected, by the aid of which the Committee were subsequently enabled to state their conclusions with definiteness. During these investigations intensities were shown in a single oil and gas luminary about three times greater than the electric arc luminary first adopted at Dungeness in 1861, while, with a single electric arc luminary, there was shown a practically available focal intensity about fifteen times greater than that of the Dungeness luminary, and the highest yet shown to be practically available for the service of the mariner.

With gas and oil the highest intensity of a single luminary and optical apparatus was tripled by the use of three superposed luminaries and optical apparatus, and although optical arrangements were made for triple electric luminaries, and experiments were carried out with these at comparatively low intensities, it was soon found that all the electromotive force available at the station could be conveniently applied with efficiency and permanency in one compact focal luminary, and its optical apparatus. This fact demonstrated that the electric arc has the most important requisites of a lighthouse luminary; viz. maximum intensity and minimum focal dimensions, and in all states of the atmosphere, from clear weather to thick fog, an incontestable superiority over the utmost accumulative efforts of its rivals—gas and oil. It was therefore considered to be unnecessary to incur additional cost for exhibiting the electric arc light, under the same conditions of accumulative powers as its rivals, for showing a maximum intensity. With the best gas and oil luminaries it was found that, where gas of the ordinary commercial quality is employed, there is no appreciable difference, either in the intensity or focal compactness of the luminary, but when the richest gas, from cannel coal, and mineral oil are used, there is found to be a superiority in the maximum intensity of this luminary over oil of about 45 per cent., and in focal compactness of about 10 per cent.; but in haze and fog, when the maximum intensity only is required, this difference was found to effect no appreciable gain in penetrative power, therefore the question of merit between these illuminants was found to resolve itself into one of economy only, and in this respect mineral oil at the present market prices was found to have a considerable advantage.

The relative penetrability per unit of light of the best gas and oil flames in haze and fog is so nearly identical that the question is of no practical importance in lighthouse illumination. But, with regard to the relative atmospheric absorption of these lights and the electric arc light in certain impaired conditions of the atmosphere, the electric arc light is found to compare somewhat unfavourably. The general result of the photometric measurements of the three illuminants showed (1) that the oil and gas lights, when shown through similar lenses, were equally affected by atmospheric variation; (2) that the electric light is absorbed more largely by haze and fog than either the oil or the gas light; and (3) that all three are nearly equally affected by rain. Experiments made in the photometric gallery at the South Foreland with the electric arc light have shown that the loss by atmospheric absorption is by no means so great as was previously supposed. It would have been most interesting and instructive to have obtained data for exactly determining the relative coefficients of atmospheric absorption of the electric arc, gas, and oil luminaries, but the necessary observations and measurements for effecting this would have prolonged the time too much, and added too much to the cost of the investigation, especially when it is remembered that with the electric arc light there is for coast illumination such an enormous preponderance of initial intensity at disposal that a small percentage of penetrating efficiency is of no practical importance.

In 1836 Faraday showed by actual experiment that the penetrating power of a light in atmosphere impaired by such obstruction as fog, mist, &c., is but very slightly augmented by a very considerable increase in the intensity, and M. Allard, late Engineer-in-Chief to the French Lighthouse Board, has more recently shown after long experimental and practical research, that, in an atmosphere of average transparency, a beam of light equal to 6250 becs (Carcel) would penetrate 53 kilometres, yet when augmented to twenty times that intensity, or 125,000 becs (Carcel), it would only penetrate 75·40 kilometres; showing that, in the average condition of atmospheric transparency, 2000 per cent. of increased intensity only gives 42 per cent. longer range.

The South Foreland experiments have demonstrated that, while with both gas and oil an ordinary intensity of light can be adopted for clear weather sufficient to reach the sea horizon with efficiency for the mariner, a maximum light can be shown with impaired atmosphere fifteen to twenty times this intensity, and that in these respects both illuminants are practically on an equality. This maximum light of gas and oil is considered by the Committee to be sufficient for all the ordinary purposes of navigation, and, for this, mineral oil is the most economical illuminant; but for some special cases, where the utmost intensity and penetration are demanded, these results can only be attained by electricity, and by this agent an intensity more than ten times that of the maximum of either oil or gas is found to be practically available.

With regard to the gas and oil lights, the report of the Committee states that "It appears from the direct eye-observations, made at distances varying from 3 to 27 miles in clear weather, that through annular lenses, light for light, there is practically no difference. Both reach the horizon with equal effect. In weather not clear the records indicate practically the same relation. In actual fog, again, the records indicate a general equality of the lights. Both are lost at the same time, both are picked up together; and although here and there a very slight superiority is attributed to the gas, this superiority is of no value whatever for the purposes of the mariner." A point referred to in favour of gas is the well-known one of greater handiness and ease of manipulation than oil, which is of importance for small beacon lights, where a constant attendant is not provided; but this does not apply to a coast light, where a light-keeper is always required to be on the watch in the lantern from sunset to sunrise. With oil the great advantage, in addition to economy, lies in the simplicity of its application to a coast lighthouse in

any part of the world, however limited the space the lighthouse is necessarily required to occupy. The final conclusion of the Committee on the relative merits of electricity, gas, and oil as lighthouse illuminants is given in the following words:—"That, for ordinary necessities of lighthouse illumination, mineral oil is the most suitable and economical illuminant, and that for salient headlands, important landfalls, and places where a very powerful light is required, electricity offers the greatest advantages."

In conclusion it may safely be asserted, now that the relative merits of electricity, gas, and oil have been accurately determined, that these investigations of the Trinity House Committee will, for many years to come, furnish to the lighthouse authorities of all maritime nations of the world, and their engineers, very valuable data which cannot fail to assist very largely in the development of lighthouse illumination, and thus tend very materially to present aids to navigation, and to a consequent reduction in the loss of life and property at sea.

REPORTS

Third Report of the Committee, consisting of Prof. Balfour Stewart (Secretary), Mr. J. Knox Laughton, Mr. G. J. Symons, Mr. R. H. Scott, and Mr. Johnstone Stoney, appointed for the Purpose of co-operating with Mr. E. J. Lowe in his Project of establishing on a Permanent and Scientific Basis a Meteorological Observatory near Chepstow.—In answer to a letter written by Prof. Balfour Stewart, pointing out certain conditions indispensable to the success of the project, Mr. Lowe writes:—"The (local) Committee think that they see their way to getting two or three thousand pounds if the scheme were started. Since you were with me I have purchased nearly 150 acres of land in front of the observatory, and nothing could come between it and the channel as near as $1\frac{1}{2}$ to 2 miles. A new road is to be made to the Severn Tunnel Station, and I hear that the telegraph or telephone is likely to be carried up this road. If your Committee think well to recommend the observatory scheme, action would be at once taken, and we have reason to believe that the Bristol Docks would help us with 100*l.* a year. I should much like to see such an observatory in working order whilst I live, but my time is getting short. There is a growing interest round here about the observatory, and constant inquiries are made as to the probabilities of success." The Committee express their sympathy with Mr. Lowe and his friends under the unfortunate circumstances that have tended to retard local action. The Committee see such evidence of local interest in the undertaking that they desire to have an early opportunity of co-operating with the local Committee. They therefore ask for their re-appointment, and request that the unexpended sum of 25*l.* and an additional sum of the same amount—in all 50*l.*—be placed at their disposal for the purpo e.

A Report of the Committee consisting of Profs. Tilden and Ramsay and Dr. Nicol (Secretary), appointed for the Purpose of Investigating the Subject of Vapour-Pressures and Refractive Indices of Salt Solutions, was read by Dr. Nicol.—The report deals with the general conclusions arrived at from recent experiments on vapour-pressures, rates of expansion, refractive indices, and saturation of salt solutions. The experiments on the vapour-pressure of salt solutions completely disprove the statement of Wüllner, that the diminution of vapour-pressure is directly proportional to the percentage of salt present; in some cases it has been observed that the restraining effect of each molecule increased with the concentration, whilst with other salts it decreased on the addition of salt even in dilute solutions. Such results can, however, be readily explained by the theory of solution proposed by Nicol in the *Philosophical Magazine*, 1883.

The Report of the Committee consisting of Profs. Ramsay, Tilden, W. L. Goodwin (Secretary) and D. H. Marshall, appointed for the Purpose of Investigating Certain Physical Constants of Solutions, was read by Prof. Ramsay.—This report contained an account of an investigation conducted by Profs. Goodwin and Marshall of the Queen's Univerity, Kingston, Ontario, the object of which was the determination of the condition of equilibrium assumed by molecular weights of two salts placed in separate small vessels and inclosed with a weighed quantity of water. The process by which the water is so attracted to the alts was styled "invaporation" by Graham. The salts experimented with were the chlorides of potassium, lithium, and sodium. When sodium and potassium chlorides were used, and different quantities of water, it was found that sodium chloride invaporates the water more rapidly than potassium chloride, and that, with small relative quantities of water, the sodium chloride invaporates nearly all and leaves the potassium chloride almost dry. When this is compared with the state of equilibrium assumed by equivalents of caustic soda, caustic potash, and sulphuric acid in solution together, it seems that the force in the first case is different in character from that acting in the second. Similar experiments made with sodium and lithium chlorides, and varying the relative quantities of water, showed that with small relative quantities of water the lithium chloride attracted the whole, but with larger quantities the sodium chloride attracts part, showing that in this case there is a limit to the quantity of water which the lithium chloride can hold against the attraction of sodium chloride. When the relative quantity of water is small, it is not divided between the two salts in the ratio of their attraction for water; but this may be the case with large relative quantities of water. The process of invaporation is in all cases very slow, in some cases requiring several months for its completion. A further investigation of these phenomena with other salts, and a study of the influence of temperature is promised.

A Preliminary Report of the Committee consisting of Profs. McLeod and Ramsay, with Mr. W. A. Shenstone as Secretary, appointed for the Further Investigation of the Influence of the Silent Discharge of Electricity on Oxygen and other Gases, was read by Mr. Shenstone.—A description was given of the apparatus devised for the storage and convenient manipulation of oxygen, so as to insure its perfect purity. The use of a mixture in molecular proportions of potassium and sodium chlorates is recommended in the preparation of oxygen, inasmuch as the breakage of apparatus, when potassium chlorate alone is used, is to a great extent done away with.

The Report of the Committee consisting of Profs. W. A. Tilden and H. E. Armstrong, appointed for the Purpose of Investigating Isomeric Naphthalene Derivatives, of which Prof. H. E. Armstrong is the Secretary, was read by the latter, who pointed out that, owing to its constitution, naphthalene lends itself very easily to the production of isomeric compounds. The constitution of the disulphonic acids of naphthalene has been specially investigated, and four isomeric compounds were described, as were also several isomeric bromo-derivatives.

The Committee consisting of Prof. Sir H. E. Roscoe, Mr. Lockyer, Profs. Dewar, Liveing, Schuster, W. N. Hartley, and Wolcott Gibbs, Capt. Abney, and Dr. Marshall Watts, appointed for the Purpose of Preparing a New Series of Wave-Length Tables of the Spectra of the Elements, of which Dr. Marshall Watts is the Secretary, reported that satisfactory progress had been made during the past year with the work allotted to it, and that the forthcoming volume of the *Proceedings* of the Association will contain additions to the tables of wave-lengths of the emission spectra of the elements and compounds.

Report of a Committee, consisting of General J. T. Walker, General Sir J. H. Lefroy, Prof. Sir William Thomson, Mr. Francis Galton, Mr. Alex. Buchan, Mr. J. Y. Buchanan, Dr. John Murray, Mr. H. W. Bates, and Mr. E. G. Ravenstein (Secretary), appointed for the Purpose of taking into Consideration the Combination of the Ordnance and Admiralty Surveys, and the Production of a Bathy-hypsographical Map of the British Isles.—(1) The Committee consider that the production of a plain outline map of the British Isles and surrounding seas, on a scale of 1 : 200,000 (about three miles to the inch) would be desirable. Rivers, and such other physical features as can be shown in outline, to be marked distinctly. No hill-shading to be introduced. Roads, railways, towns, &c., to be indicated faintly, and merely for the purpose of identifying localities. Principal heights and depths above and below the datum level of the Ordnance Survey of Great Britain to be inserted. Contours to be drawn at intervals of 200 feet, with subsidiary contours where they are necessary, to give expression to the features of the ground. Incidental features, such as cliffs, &c., to be marked. The map to be tinted according to height (2) A grant of 25*l.* to be applied for in order that a specimen sheet of the map may be prepared. (3) The Clyde Trustees to be approached, with a view to their undertaking the preparation of a similar map of the Clyde estuary on a suitably larger scale. Other harbour Boards to be similarly approached.

(4) The Committee anticipate that, being provided with maps of this character as specimens of what is required to supply a national want, the Association may be in a better position than at present to move the Government to undertake the preparation of a similar map of the whole of the United Kingdom, based mainly upon the extensive data already available in the archives of the Ordnance Survey and the Admiralty.

Report of the Committee, consisting of Dr. J. H. Gladstone (Secretary), Prof. Armstrong, Mr. William Shaen, Mr. Stephen Bourne, Miss Lydia Becker, Sir John Lubbock, Bart., Dr. H. W. Crosskey, Sir Richard Temple, Sir Henry E. Roscoe, Mr. James Heywood, and Prof. N. Story-Maskelyne, appointed for the Purpose of Continuing the Inquiries Relating to the Teaching of Science in Elementary Schools.—No steps in advance have been taken by any Government Department towards the more adequate provision for science-teaching in elementary schools during the past year. There have been four different Vice-Presidents of the Committee of Council on Education during the last twelve months; and Sir Lyon Playfair only came into office after the Code for the year had been settled. The annual return of the Education Department for England and Wales issued this year, which deals with the period from September 1, 1884, to August 31, 1885, shows that the present regulations tell unfavourably on the prospects of science. The following statistics for the last three years show that, while the preferential class subject "English" is taken in an increasing number of departments year by year, geography shows an actual falling off, and elementary science seems even to be losing the little footing it had. Needlework shows a steady increase, as it is an obligatory subject in girls' schools, and it is more advantageous in a financial point of view to take it up as a class subject rather than under Article 109 (*c*), in which case it necessarily displaces geography or science:—

Class Subjects	1882-83 Departments	1883-84 Departments	1884-85 Departments
English	18,363	19,080	19,431
Geography	12,823	12,775	12,336
Elementary Science	48	51	45
History	367	382	386
Needlework	5,286	5,929	6,499
	18,524	19,137	19,266

In regard to the scientific specific subjects, the following are the number of children individually examined:—

Specific Subjects	1882-83 Children	1883-84 Children	1884-85 Children
Algebra	26,547	24,787	25,347
Euclid and Mensuration	1,942	2,010	1,269
Mechanics, A	2,042	3,174	3,527
,, B	—	206	239
Animal Physiology	22,559	22,857	20,869
Botany	3,280	2,604	2,415
Principles of Agriculture	1,357	1,859	1,481
Chemistry	1,183	1,047	1,095
Sound, Light, and Heat	630	1,253	1,231
Magnetism and Electricity	3,643	3,244	2,864

	82,965	84,515	79,774

No of Scholars in Standards V., VI., VII.	286,355	325,205	352,860

It is evident that while the number of scholars in the higher standards has considerably increased, the number examined in specific (scientific) subjects has considerably decreased; and this decrease has occurred in every subject except mechanics. Algebra and chemistry show rather larger numbers than last year, though not in proportion to the increase of scholars. The comparative decrease in the attention paid to these scientific subjects will be evident from the percentages of children examined:—

In 1882–83	29·0 per cent.
In 1883–84	26·0 ,,
In 1884–85	22·6 ,,

but it must be borne in mind that in many schools the children take two subjects, in which case they count accordingly. Increased though still very inadequate attention seems to be paid in the training colleges to the preparation of the students in the science subjects; the number of individual students who have qualified for teaching one or more sciences has risen from 2205 in 1884 to 2407 in 1885, and it is satisfactory to note that the increase has been mainly in passes in the first class. The number of papers worked in the several subjects in the two years under review have been as follows:—

Number of papers worked	1884	1885
Pure Mathematics	82	121
Theoretical Mechanics	21	25
Sound, Light, and Heat	488	690
Magnetism and Electricity	693	551
Inorganic Chemistry	245	269
,, ,, (practical)	166	160
Animal Physiology	416	257
Botany	485	483
Physiography	1030	1095
Principles of Agriculture	289	386

The increase has been mainly in sound, light, and heat, and the principles of agriculture; the falling off has been chiefly in animal physiology, and magnetism and electricity. The Scotch Code differs from the English in regard to the teaching of science in several points, but the annual return does not exhibit a much more hopeful state of affairs. The importance of technical instruction is making rapid progress in popular estimation, but this subject has not got a real footing as yet in elementary schools, owing to the inaction of the Government pending a definite expression of opinion by the House of Commons.

SECTION A—MATHEMATICAL AND PHYSICAL SCIENCE

On Stationary Waves in Flowing Water, Part I., by Sir William Thomson.—This subject includes the beautiful wave-group produced by a ship propelled uniformly through previously still water, but the present communication[1] is limited to two-dimensional motion

Imagine frictionless water flowing in uniform *régime* through an infinitely long canal with vertical sides; and bottom horizontal except where modified by transverse ridges or hollows, or slopes between portions of horizontal bottom at different levels. Included among such inequalities we may suppose bars above the bottom, fixed perpendicularly between the sides. Let these inequalities be all within a finite portion, AB, of the length, and let f denote the difference of levels of the bottom on the two sides of this portion, positive if the bottom beyond A is higher than the bottom beyond B.

Now, let the water be given at an infinite, or very great, distance beyond A, perpetually flowing towards A with any prescribed constant velocity, V, and filling up the canal to a prescribed constant depth, D. It is required to find the motion of the water towards A, through AB, and beyond B as disturbed by the inequalities between A and B. This problem is essentially determinate; and it has only one solution if we confine it to cases in which the vertical component of the water's velocity is everywhere small in comparison with $\sqrt{gD}$, the velocity acquired by a falling body falling from a height equal to half the depth.

In particular cases the water flows away unruffled at great distances from B. But, in general, the surface is ruffled, and the water flows "*steadily*" between the plane bottom and a corrugated free surface, as in the well-known appearance of water flowing in a mill-lead, or Highland burn, or in the clear rivulet on the east side of Trumpington Street, Cambridge. The train of diminishing waves which we see in the wake of each little irregularity of the bottom would, of course, extend to infinity if the stream were infinitely long, and the water absolutely inviscid (frictionless); and a single inequality, or group of inequalities, in any part, AB, of the stream, would give rise to corrugation in the whole of the flow after passing the inequalities, more and more nearly uniform, and with ridges and hollows more and more perpendicular to the sides of the canal, the farther we are from the last of the inequalities. Observation, with a little common-sense of the mathematical kind, shows

[1] I have since found, in a sufficiently practical form, the solution for the wave-group produced by the ship, which I hope to communicate to the *Philosophical Magazine* for publication in the November number.—W. T., September 13, 1886.

that at a distance of two or three wave-lengths from the last of the irregularities if the breadth of the canal is small in comparison with the wave-length, or at a distance of nine or ten breadths of the canal if the breadth is large in comparison with the wave-length, the condition of uniform corrugations with straight ridges perpendicular to the sides of the canal, would be fairly well approximated to, even though the irregularity were a single projection or hollow in the middle of the stream. But the subject of the present communication is simpler, as it is limited to two-dimensional motion; and our inequalities are bars, or ridges, or hollows, perpendicular to the sides of the canal. Thus, in our present case, we see that the condition of ultimate uniformity of the standing waves in the wake of the irregularities is closely approximated to at a distance of two or three wave-lengths from the last of the inequalities.

A mathematical treatment of the problem thus presented, which will appear in the October number of the *Philosophical Magazine*, gives, among other results, the following conclusions:—

Generally, in every case when $V < \sqrt{gD}$ the upper surface of the water rises when the bottom falls, and the water falls when the bottom rises.

On the other hand, when $V > \sqrt{gD}$, the water surface rises convex over every projection of the bottom, and falls concave over hollows of the bottom; and the rise and fall of the water are each greater in amount than the rise and fall of the bottom; so that the water is deeper over elevations of the bottom, and is shallower over depressions of the bottom.

Returning now to the subject of standing waves (or corrugations of the surface) of frictionless water flowing over a horizontal bottom of a canal with vertical sides, I shall not at present enter on the mathematical analysis by which the effect of a given set of inequalities within a limited space, AB, of the canal's length, in producing such corrugation in the water after passing such inequalities, can be calculated, provided the slopes of the inequalities and of the surface corrugations are everywhere very small fractions of a radian. I hope before long to communicate a paper to the *Philosophical Magazine* on this subject for publication. I shall only just now make the following remarks:—

(1) Any set of inequalities large or small must in general give rise to stationary corrugations large or small, but perfectly stationary, however large, short of the limit that would produce infinite convex curvature (according to Stokes's theory an obtuse angle of 120°) at any transverse line of the water surface.

(2) But in particular cases the water flowing away from the inequalities may be perfectly smooth and horizontal. This is obvious because of the following reasons:—

(i.) If water is flowing over plane bottom with infinitesimal corrugations, an inequality which could produce such corrugations may be placed on the bottom so as either to double those previously existing corrugations of the surface or to annul them.

(ii.) The wave-length (that is to say, the length from crest to crest) is a determinate function of the mean depth of the water and of the height of the corrugations above it, and of the volume of water flowing per unit of time. This function is determined graphically in Stokes's theory of finite waves. It is independent of the height, and is given by the well-known formula when the height is infinitesimal.

(iii.) From No. ii. it follows that, as it is always possible to diminish the height of the corrugations by properly adjusted obstacles in the bottom, it is always possible to annul them.

(3) The fundamental principle in this mode of considering the subject is that, whatever disturbance there may be in a perpetually sustained stream, the motion becomes ultimately steady, all agitations being carried away down stream, because the velocity of propagation, relatively to the water, of waves of less than the critical length, is less than the velocity of flow of the water relatively to the canal.

In Part II., to be published in the November number of the *Philosophical Magazine*, the integral horizontal component of fluid pressure on any number of inequalities in the bottom, or bars, will be found from consideration of the work done in generating stationary waves, and the obvious application to the work done by wave-making in towing a boat through a canal will be considered. The definitive investigation of the wave-making effect when the inequalities in the bottom are geometrically defined, to which I have just now referred, will follow; and I hope to include in Part II., or at all events in Part III. to be published in December, a complete investigation, illustrated by drawings, of the beautiful pattern of waves produced by a ship propelled uniformly through calm deep water.

On a New Form of Current-Weigher for the Absolute Determination of the Strength of an Electric Current, by Prof. James Blyth.—The object of this paper is to describe a method of absolutely determining the strength of an electric current by measuring in grammes' weight the electro-magnetic force between two parallel circular circuits, each carrying the same current. For convenience of calculation the circles have the same radius, and are placed with their planes horizontal. The construction of the instrument is as follows:—A delicate chemical balance is provided, and the scale-pans replaced by two suspended coils of wire. Each of these is made of a single turn of insulated copper wire (No. 16 about) fixed in a groove round the edge of an annular disk of glass or brass of suitable diameter. The disk is made as thin and light as possible consistently with perfect rigidity. By means of two vertical pillars of brass this annulus is attached to a rigid cross-bar of dry wood or vulcanite, in the middle of which is placed a hook for suspending the whole from one end of the balance-beam. On each side of the hook, and equally distant from it, two slender rods of brass are screwed in in the wooden bar, which support two small platinum cups for holding mercury or dilute acid. The position of these cups is so adjusted that, when the whole hangs freely, the cups are in line with the terminal knife-edge of the balance-beam, and have their edges just slightly above its level. The free ends of the insulated wire surrounding the disk, after being firmly tied together for a considerable length and suitably bent, are soldered to the brass supports of the platinum cups, which thus serve as electrodes by means of which a current may be sent through the suspended coil. A precisely similar coil is suspended from the other end of the balance-beam. We now come to the arrangement by means of which a current is led through the suspended coils, so as to interfere as little as possible with the sensibility of the balance. This constitutes the essential peculiarity of the instrument, and is effected in the following way:—An insulated copper wire, having its ends tipped with short lengths of platinum, is run along the lower edge of the beam, and is firmly lashed to it by well-rosined silk thread. The ends of this wire, bent twice at right angles, are so placed that their platinum tips dip vertically into one of each pair of the platinum cups which are attached to the vertical rods of the suspended coils. From the other cup of each pair proceed two similarly tipped copper wires, which run along the upper edge of the beam, and are also firmly tied to it. These wires, however, only proceed as far as the middle of the beam, where they are bent, first outwards, one on each side of the beam, at right angles to it, and then downwards, so that the platinum tips are vertical. The latter dip into two platinum cups attached to two vertical rods, which spring from the base-board of the balance. These rods are placed at equal distances on each side of the beam, and are of such length that the platinum cups are in line with the central knife-edge of the beam and have their edges just a little above its level. There are thus in all six cups and six dipping wires. Three of these are in line on one side of the beam, and three on the other. Also the line joining the points of each pair of dipping wires is made to coincide with the corresponding knife-edge; and, further, the edges of the cups are all in the same plane when the balance is in equilibrium. From this it will be obvious that any motion of the beam in the act of weighing causes only a very slight motion of the platinum wires, which dip into the fluid contained in the cups. The resistance, due to the viscosity of the fluid, is thus very small, even in the case of mercury, and much smaller still when dilute acid is used. In point of fact, the diminution of sensibility due to this cause is less than in the case of determining the specific gravity of solids by weighing in water in the ordinary way. With clean mercury it is quite easy to weigh accurately to a milligramme. The fixed coils, constituting two pairs, have the same diameter as the suspended coils, and, like them, are made of single turns of insulated wire wound round the edges of circular disks of glass or brass. The disks of each pair are fixed at the requisite distance apart to a cylindrical block of wood, so as to have their planes exactly parallel and their centres in the same straight line. To insure this they are turned up and finished on the same cylindrical block on which they are finally to rest. When in position they are so placed that, when the balance is in equilibrium, each suspended coil hangs perfectly free to move with its plane horizontal and exactly midway between a pair of fixed coils. For

this purpose, as will be seen, it is necessary that two large holes be drilled in the upper disk of each pair, so as to allow the brass pillars of the corresponding annular disk to pass freely through. When the connections are made, the current is led through the entire apparatus in such a way that, while the electromagnetic force acting on the one suspended coil causes it to descend, the electro-magnetic force acting upon the other causes them to ascend. The total force tending to disturb the equilibrium of the balance is thus exactly four times that due to an equal current circulating in two parallel circles of the same diameter and with their planes at the same distance apart. The current-strength is estimated from the number of grammes required to restore the balance to exact equilibrium, the weights being placed into small scale-pans attached to the movable part of the apparatus. The electro-magnetic force between each fixed and the corresponding suspended coil is calculated from the formulæ given by Clerk Maxwell (vol. ii. p. 308), viz. :—

$$\frac{dM}{db} = -2\pi \cos\gamma \left\{2F\gamma - (1 + \sec^2\gamma)\,E\gamma\right\}$$

where M = the potential energy between two parallel circles, each carrying unit current,

b = distance between their planes,

a = radius of each coil,

$$\sin\gamma = \frac{2a}{\sqrt{4^2a + b^2}},$$

$F\gamma$ and $E\gamma$ = first and second complete elliptic integrals to modulus $\sin\gamma$.

In one of the instruments constructed

$$a = 10{\cdot}8 \text{ inches}, \; b = {\cdot}566 \text{ inches},$$

which give

$$\gamma = 87^\circ,\; F\gamma = 4{\cdot}338653976,\; E\gamma = 1{\cdot}00525857\,;$$

from which, if G denote the constant of the instrument and $g = 981$, we have

$$G = 4 \,.\, \frac{dM}{db} \,.\, \frac{1}{g} = {\cdot}4818.$$

This gives for 1 ampere a force = ·04818 gramme-weight.

Besides the one exhibited I have constructed several modifications of the instrument, only one of which, however, needs be particularly mentioned. In it both the fixed and movable coils are replaced by flat spirals of wire, each of eleven turns. Here the practical construction is more difficult, and the calculation of the constant somewhat more laborious, unless one is content with merely integrating over the area of both the fixed and suspended spirals. This is, I think, however, hardly legitimate, at least with thickish wires, as we thereby suppose that electricity is circulating in the insulating spaces between the wires as well as in the wires themselves. To avoid this I have actually calculated the force exerted by each one of the coils of the fixed spiral upon each coil of the suspended spiral. This entails great labour, as the elliptic integrals have to be calculated for values of the modulus differing very slightly from each other. The labour, however, is worth the taking, as the attractive or repulsive force between two flat spirals is so much greater than that between two simple circles.

The Peculiar Sunrise-Shadow o Adam's Peak in Ceylon, by the Hon. Ralph Abercromby, F.R.Met.Soc.—A great peculiarity has been noticed by many travellers about the shadow of Adam's Peak at sunrise. The shadow, instead of lying flat on the ground, appears to rise up like a veil in front of the spectator, and then suddenly to fall down to its proper level. Various theories have been propounded to account for this, and it has usually been supposed to be due to a sort of mirage. The author, in the course of a meteorological tour round the world, spent the night on the top of the peak, 7352 feet above the sea, and obtained unmistakable evidence that the appearance is due to light wreaths of thin morning mist being driven past the western side of the mountain by the prevailing north-east monsoon up a neighbouring gorge. The shadow is caught by the mist at a higher level than the earth, and then falls to its own plane on the ground as the condensed vapour moves on. The appearance is peculiar to Adam's Peak ; for the proper combination of a high isolated pyramid, a prevailing wind, and a valley to direct suitable mist at a proper height on the western side of a mountain, is only rarely met with. Any idea that the appearance could be caused by mirage is completely disproved by the author's thermometric observations.

Description of a New Calorimeter for Lecture-Purposes, by T. J. Baker.—The instrument consists of two exactly similar metallic air-thermometers mounted side by side with their U-shaped thermometer-tubes adjacent, so that their indications can be easily compared with each other. The air-vessel of each thermometer contains a cylindrical well, in which the substance to be experimented with is immersed. Each well is provided with a discharging-tube furnished with a stop-cock. The scale common to both thermometers is of milk-glass, divided into 100 equal parts both above and below zero, and let into the stand so as to constitute a translucent window which can be illuminated from behind. By means of this instrument many thermal problems can be demonstrated before a large audience.

On the Distribution of Temperature in Loch Lomond and Loch Katrine during the past Winter and Spring, by J. T. Morrison, M.A.—The author made observations on the temperature of these lakes on or about the term day of each month from December 1885 to June 1886, in continuation of Mr. J. Y. Buchanan's researches. These included the whole length of Loch Katrine and the head and middle part of Loch Lomond, the deepest sounding, 99 fathoms, being got near Inversnaid in the latter lake. At Inversnaid, from December till March, the water was each month of uniform temperature from surface to bottom, the temperatures being—

December 22, 1885	42°·8
January 21, 1886	41·2
February 23, 1886	40·05
March 23, 1886	39·05

In the deepest sounding obtained on Loch Katrine, 79 fathoms, a similar distribution was met with up till February, the readings being—

December 23, 1885	(42°·3) [1]
January 22, 1886	40·4
February 24, 1886	39·0

And, though the maximum density-point was thus attained in February, uniformity still prevailed in March down to a depth of 70 fathoms, the readings on March 24 being : surface, 38°·1 ; 70 fathoms, 38°·1 ; 79 fathoms, 38°·7. In April the temperature distribution usually found in spring had set in in both lakes, the surface being warmest, the bottom coldest, and the temperature falling more and more slowly with increase of depth. The circumstance of most interest, however, is that the warmth of the bottom layer increased monthly over the deepest parts of both lakes, as follows :—

	March	April	May	June
	°	°	°	°
Loch Lomond (99 fathoms)	39·05	39·4	40·3	40·6
Loch Katrine (79 fathoms)	38·7	39·1	40·1	40·65

This rise is evidently due not to the conduction of heat nor to the penetration of solar radiation, but to some drainage or oozing causing mixture. This supposition seems necessary also to explain the behaviour of Loch Katrine in March. Drainage *en masse* appears to occur chiefly in winter and spring, not in summer when the river water and the lake surface water are much warmer than the deep water of the lake. The mean temperature of Loch Katrine probably has a greater range than that of Loch Lomond. The shallower parts of the lakes resemble the deep parts as to uniformity of temperature up till March. But their yearly range is greater. In both lakes the mean temperature becomes uniform along the whole length about April 4.

On the Distribution of Temperature in the Firth of Clyde in April and June 1886, by J. T. Morrison, M.A.—In the latter parts of April and June of this year Mr. John Murray, Dr. Mill, and the author made serial temperature soundings throughout the Clyde district, chiefly with Negretti and Zambra's reversing thermometer. It was found that in matter of temperature the waters of the district were divisible into four groups : I. North Channel and the plateau south of Arran ; II. the Arran and Dunoon open basins ; III. the deep-sea lochs ; IV. the shallow sea lochs. The average temperature in each group at every depth was calculated for April and June, and these averages form the basis of this paper. In April in all groups there is a deep layer of uniform temperature overlaid by a layer of temperature rising steadily to the surface. In groups II., III., and IV. the uniform deep temperatures are almost the same, about 41°·4 F. ; in group I. it is 41°·8 F. In June the superficial

[1] No sounding made here in December. Above temperature is calculated from that of another part of the lake.

layer of varying temperature had thickened to about 20 fathoms. The deep temperatures in the groups were now very different:—

	I.	II.	III.	IV.
Deep temperature in April ...	41·8	41·3	41·5	41·5[1]
,, ,, June ...	46·7	43·9	43·8	45·3[1]
Rise of temperature	4·9	2·6	2·3	3·8

To groups III. and IV. analogues are found in a deep and a shallow basin of Loch Lomond, in both of which the bottom temperature rose between April and June. From this it is inferred that land-influences, especially drainage *en masse*, produce most of the effect noticed in III. and IV. The great rise in the North Channel and southern plateau is evidently due to a warm oceanic current. The rise in temperature in group II. is due to the incoming of warm water from without. As the water between 30 and 75 fathoms in this group is very uniform in temperature, and as the south plateau is 25 fathoms below the surface, it is supposed that the dense plateau water is carried into the open basins (group II.), and through convection mixes thoroughly the water below 30 fathoms there. Loch Goil is specially remarkable for its isolation and the small rise of bottom temperature —0°·6 F. in two months. In Upper Loch Fyne a lenticular mass of water below 43°·0 F. was found in June to float between two warmer layers. Its greatest thickness, 30 fathoms, was opposite Inverary. The bottom layer of 44°·0 F. was not found to be in connection with any equally warm layer either inside or outside of the loch.

On the Critical Curvature of Liquid Surfaces of Revolution, by A. W. Rücker, M.A., F.R.S.—Let a mass of liquid film be attached to two equal circular rings, the planes of which are perpendicular to the line joining their centres. It will form a surface of revolution the equation of which is, according to Beer,—

$$y^2 = \alpha^2 \cos^2 \phi + \beta^2 \sin \phi,$$
$$x = \alpha \mathrm{E} + \beta \mathrm{F},$$

where F and E are elliptic integrals of the first and second kinds respectively, the amplitude being ϕ, and the modulus $\kappa = \sqrt{\alpha^2 - \beta^2}/\alpha = \sin \theta$. If θ be conceived as increasing from 0, when it is in the first quadrant the figure will be an unduloid lying being the cylinder and the sphere, in the second quadrant a nodoid, the limits of which are the sphere and a circle. In the third and fourth quadrants the figure will be dice-box-shaped with a contraction in the middle, being a nodoid in the third and an unduloid in the fourth quadrant. The one passes into the other through the catenoid. If now we suppose the rings to be at a fixed distance apart, and the volume of the surface to be altered, the curvature will change, and the direction of the change will depend on the diameter and distance apart of the rings, and on the magnitude of the maximum or minimum ordinate (the *principal ordinate*), which lies half-way between them. The object of the paper is to investigate the general relation between these quantities when the curvature is a maximum or minimum, if the changes in the form of the film take place subject to the conditions that the diameter and distance of the rings are constant. It has been recently shown by Prof. Reinold and the author that, if these conditions hold,

$$(\alpha^2\mathrm{E} - \beta^2\mathrm{F} + \alpha^2\Delta_1 \cot \phi_1)\delta\alpha + \alpha^2(\mathrm{F} - \mathrm{E} + \Delta_1 \tan \phi_1)\delta\beta = 0,$$

where ϕ_1 is the upper limit of the integrals and

$$\Delta_1 = \sqrt{1 - \sin^2 \theta \sin^2 \phi_1}.$$

Writing this in the form $\mathrm{A}\delta\alpha + \mathrm{B}\delta\beta = 0$, it is proved that the curvature has in general a critical value when $\mathrm{A} - \mathrm{B} = 0$; so that

$$2\mathrm{E} - \mathrm{F}(1 + \cos^2 \theta) + 2\Delta_1 \cot 2\phi_1 = 0$$

is a condition which must be satisfied by θ and ϕ_1. To find values of ϕ_1 corresponding to given values of θ the equation must be solved by trial; but it is proved that, if a pair of corresponding values is given when θ lies (say) in the first quadrant, the values of ϕ_1 can be at once found which correspond to $\pi - \theta$, $\pi + \theta$, and $2\pi - \theta$. The values of ϕ_1 corresponding to θ and $\pi - \theta$ are equal, and, if ϕ_2 be the value corresponding to $\pi + \theta$ and $\pi - \theta$, it is given by the equation

$$\tan \phi_1 \tan (\pi - \phi_2) = \sec \theta.$$

By means of these equations a curve can be drawn, showing the relations between ϕ_1 and θ, and thence are found the values of p/Y, X/p, and X/Y, where $2\mathrm{Y}$, $2\mathrm{X}$, and $2p$ are the diameter and distance of the rings and the magnitude of the principal diameter. If we now conceive the two rings gradually to approach or recede from each other, and the principal diameter to be altered so that the condition of critical curvature is always fulfilled, it is proved that the changes in its form would be as follows:—Beginning with the cylinder, the distance of the rings would (as has been shown by Maxwell, Art. "Capillarity," "Enc. Brit.") be half their circumference. As the diameter increases, the rings would move apart, and the distance between them would be a maximum when $\theta = 64°·2$, being 17 per cent. greater than in the case of the cylinder. When $\theta = 90°$, the figure is a sphere, and the distance between the rings is about 4 per cent. less than in the case of the cylinder. The sphere has a larger diameter than any other figure of critical curvature. The surface next becomes a nodoid, and the distance between the rings diminishes till when $\theta = 180°$ they touch, and thus the surface reduces to a circle. In the next quadrant the rings separate, but the figure is now dice-box-shaped, and the pressure exerted by the film is outwards. When $\theta = 270°$, the figure is the catenoid. The principal ordinate is then less than that of any other figure of critical curvature, and the radius of the rings is a mean proportion between this minimum ordinate and the maximum which was attained in the case of the sphere. The same relation holds between the principal ordinates of any two figures which correspond to values of θ which differ by 180°. In the fourth quadrant the figure becomes an unduloid, the pressure is inwards, the rings continue to separate, and the ratio of the distance between the rings to the principal ordinate is a maximum when $\theta =$. In the paper tables and curves are given to illustrate the "march" of these functions. To secure continuity, the problem is discussed without reference to the question as to whether the surfaces are in stable equilibrium, though those in the first and fourth quadrants and figures corresponding to values of θ not much $> \pi/2$ and not much $< 3\pi/2$ certainly are. In conclusion it is shown that by means of the curves we can solve a number of problems with sufficient accuracy for practical purposes. Thus, if any two of the three quantities, the diameter of the rings, the distance between them, and the diameter of the surface of critical curvature, are given, the third can be found.

SECTION B—Chemical Science

Absorption Spectra of Uranium Salts, by Dr. W. J. Russell and W. J. Lapraik.—This paper was communicated by Dr. Russell, who pointed out that well-marked absorption bands in the visible spectrum are produced by the different salts of this metal; the bands produced by the uranous salts are distinct from those given by the uranic salts; both consist, however, of three distinct bands or groups of bands. The bands produced by the uranous salts are at the red end of the spectrum, whilst those due to the uranic salts are at the blue end; and when both classes of salts are mixed in solution there are three series of bands distributed with tolerable regularity over the whole of the spectrum. Experiments with different salts show the nature of the acid radical to have no influence on the spectrum, whereas in the case of other metals, such as cobalt, it has been found that different radicals produce different spectra. The spectrum common to all uranic salts is slightly altered by the addition of free acid; a diminution in intensity in the least refrangible bands and a slight shift in others has been observed. Crystals of uranic nitrate give an absorption spectrum similar to that produced by its solutions. The spectrum of the uranous salts is less refrangible than that of the uranic salts; the examination of the spectra produced by the uranous salts in the solid state was found to be more complex than those given by these salts in solution.

The Air of Dwellings and Schools, and its Relation to Disease, by Prof. Carnelly.—The author gave an account of an elaborate series of experiments conducted by him and Dr. Haldane at Perth and Dundee, in connection with the sanitary and school authorities, the object being to determine the relations between the composition of the air and the death-rate in houses and schools, and also the effect of various systems of ventilation. For this purpose the carbon dioxide, organic matter, and micro-organisms were determined, both in the outside air and in the room to be examined. In the air of the towns of Perth and Dundee a distinct increase of impurities could be detected in close parts of the towns as compared with the open spaces. In examining the dwelling-houses, the experimenters had authority

[1] Average temperature of first few fathoms above bottom.

from the sanitary officers, and visited bed-rooms and similar places during all parts of the day or night, while actually occupied by the inhabitants. Houses are divided in the tables into one-, two-, and four-roomed dwellings, and mention was made of some cases in single-roomed dwellings in which eight persons were found sleeping in a single bed, and in many cases no bed was found in the dwelling at all. The impurities in the air of such houses were naturally much greater than in better class, and by a careful comparison of chemical composition of the air with the death-rates from various causes in the various classes of houses, it was shown that on an average the length of life in a one-roomed house was only twenty years, whilst that in better-class houses is forty years. Hence a person born and living in a one-roomed house has a chance of living only half as long as those born and living in a four-roomed house. This depends naturally to a considerable extent on other causes than impure air-supply. Some irregularity was observed in the cases of consumption, scarlet fever, and diphtheria, which is, however, quite capable of explanation. The influence of cubic space on the purity of the air in dwelling-rooms was somewhat unexpected, the best results being noticed when 1000 cubic feet was allowed for each person. With larger rooms, owing to stagnation of the air, the result is not so good. Sixty-eight schools in Dundee were examined; of these, twenty-six were mechanically ventilated, while the others were ventilated by means of windows. The advantages were distinctly in favour of mechanical ventilation, the micro-organisms being one-seventh, and the carbon dioxide one-half of that in the other schools. Mechanical ventilation not only materially improves the quality of the air, but also has less influence in unduly reducing its temperature. On comparing together boys' and girls' schools the air is almost invariably less pure in boys' schools. The amount of carbon dioxide does not afford any indication of the amount of organic matter or micro-organisms, except by taking the mean of a large number of experiments. Cleanliness of person has a comparatively small influence on the number of micro-organisms, but cleanliness of dwelling-rooms and schools has a most important effect. Hence the air of new schools is distinctly better than that of older buildings. In conclusion, the author suggested that in many cases the evil said to be due to over-pressure in schools was doubtless due to imperfect ventilation, and that if Dundee may be fairly regarded as an example of a British town, then certainly our schools are most imperfectly ventilated; and that for improvement in this respect the advantage of mechanical ventilation should be strongly insisted upon.

The Preservation of Gases over Mercury, by H. B. Dixon, M.A., F.R.S.—From a statement in Bence-Jones's "Life of Faraday" it would appear that a difference of opinion between Faraday and Davy existed on this point, and according to the experiments of the former gases cannot be indefinitely preserved over mercury, whilst the latter found that hydrogen could be preserved over mercury for a considerable time without suffering change. The author has examined various gases, including hydrogen, cyanogen, sulphur dioxide, and electrolytic gas, which had been kept over mercury for periods ranging from 2½ to 9½ years, and concludes that the gases had suffered no change in the time.

The Distribution of the Nitrifying Organism in the Soil, by R. Warington, F.R.S.—Previous experiments have shown the limit of depth at which this organism exists in soil to be about 18 inches, but later experiments have shown it to exist at depths of 3 feet, and in some cases at depths of 5 and 6 feet.

The Fading of Water Colours, by Prof. W. N. Hartley, F.R.S.—The author, referring to the correspondence in the *Times* and to an article in the *Nineteenth Century* on this subject, pointed out that two ideas had been brought forward in connection with this matter—one being that water-colour drawings fade on keeping, while others have contended that the tints increase in depth on keeping for a length of time. Hence, on the one hand it has been recommended to keep water-colour drawings in the light, while others have suggested that darkness is preferable. Colours used are of two kinds, mineral and organic. Mineral colours are generally unalterable, except in special colours, such as lead. The tendency is for red light to act as an oxidising agent on such colours, while violet light exerts a reducing action. But in the case of organic colouring-matters oxidation is promoted by light from either end of the spectrum. Acidity in any form is a great cause of the deterioration in water-colours. The chief sources of acidity are the impurities in the atmosphere in presence of moisture, imperfectly prepared colours, and the acidity of the paper. The paper is always itself slightly acid, and the use of size or gum is a source of acidity, while the burning of coal and of gas in towns produces a sensible amount of sulphurous acid in the atmosphere. The author has carefully examined the effect of acids, of exposure to sunlight, of hydrogen peroxide, and of sulphurous acid in the case of sixteen common water-colours. As a result he concludes that the character of the colours examined is very creditable to the manufacturer. Lakes are very permanent in pure air; while cases are known where indigo has remained unchanged for upwards of 1800 years. Indigo is, however, liable to be attacked by acids. Generally the effect of chemical agents upon water-colours is what might have been expected from their chemical composition. Thus yellows containing cadmium sulphide are bleached by oxidising agents. In some few cases, however, unexpected results were obtained. Ultramarine is very readily affected by dilute acids; no preparation of lead should be used as a pigment either for oil or water-colour drawing. It is shown that many water-colour drawings have been exposed to light for fifty years or more in properly arranged galleries, without appreciable deterioration. The tendency is to produce apparently darker tints, owing to the lighter tints being most likely to fade, while the brown colour developed in the paper itself tends to produce a similar effect. To preserve delicate sunlight effects the drawings should be kept in rooms imperfectly illuminated, and preferably with blinds transmitting a yellow or brown light. They should be carefully protected from the effects of an impure atmosphere, while paste or gum should not be used in affixing them. A slight wash of borax on the paper destroys its acid reaction, and makes the colours fix readily on the fibres. A small quantity of borax might be used in the water employed for mixing the colours. For illuminating galleries incandescent lamps are to be preferred to lighting by the electric arc, as the latter may be regarded as a sure means of destruction of the colours.

The Colour of the Oxides of Cerium and its Atomic Weight, by H. Robinson, M.A.—A criticism of the work of Wolf, on the atomic weight of cerium, published in the *American Journal of Science and Art*, 1868, upon which the atomic weight, 138 cerium, given in Clark's "Constants of Nature," is based. The author contends that Wolf's method of preparation would give lanthanum and not ceric oxide; experimental evidence was given in support of this contention; further the author maintains that ceric oxide is yellow and not white, as described by Wolf.

On the Relative Stability of the Hydrochloride $C_{10}H_{17}Cl$ Prepared from Turpentine and Camphene respectively, by E. F. Ehrhardt (Mason College).—According to Ribau the first of these hydrochlorides is the less easily decomposed by water, whereas the author finds it to be the one most easily decomposed under the influence of temperature. At a low red heat Tilden has shown turpentine is more completely dissociated than camphene, and this the author has shown to be true for lower temperatures. The paradoxical result that the hydrochloride of the more stable hydrocarbon is less stable than that from the unstable one, is regarded as proving this compound to be a molecular one, in which the chlorine is associated with the hydrogen of the acid and at the same time to the hydrocarbon.

On Derivatives of Tolidine and Azotolidine Dyes, by R. F. Ruttan, B.A., M.D.—An account of the preparation of tolidine, which is the homologue of benzodine, and obtained by a similar mode of preparation. Several derivatives of this base were described, as also azotolidine or tetra-azoditolyl, which is produced by the action of nitrous acid on the base. This compound forms the starting-point in the preparation of a series of important dyes, by which cotton and wool fibre may be dyed without the use of a mordant.

On the Chemistry of Estuary Water, by H. R. Mill, D.Sc. —The salinity (ratio of total dissolved matter in water) has been determined from point to point in the Firth of Clyde and Firth of Forth. In the case of the latter the distribution of salinity has been shown to be constant all the year round, whilst in the case of the Clyde there are periodical variations through the whole mass of the water. In the case of the Forth River entrance, it is evident a mixture of river and sea water takes place by a true process of diffusion, maintaining a constant gradient from river to sea. The dissolved matter of fresher water was found richer in calcium carbonate than sea water.

The Essential Oils; a Study in Optical Chemistry, by Dr. Gladstone, F.R.S.—After explaining how the refractive equivalent of an organic compound may be used to determine its con-

stitution, the author pointed out that the dispersion equivalents can be similarly used. The author also discussed the refraction and dispersion equivalents of the turpenes, citrenes, camphor, and of some other members of the group of essential oils, and showed how these values were of service in determining the constitution of these bodies.

An Apparatus for Maintaining Constant Temperatures up to 500° C., by G. H. Bailey, D.Sc., Ph.D.—The substance to be heated is placed in a glass tube, together with the bulb of an air-thermometer, which are inclosed in a wider tube resting on the iron casing of a furnace. The air-thermometer serves to measure the temperature, and is connected with a gas regulator, by which means the temperature may be kept constant at any desired temperature below that at which combustion-glass softens.

Treatment of Phosphoric Crude Iron in Open-Hearth Furnaces, by J. W. Wailes.—The process is similar to the ordinary puddling operation, and is conducted in a furnace with a basic lining; the metal is, however, removed from the furnace in a molten condition.

Notes on the Basic Bessemer Process in South Staffordshire, by W. Hutchinson.—The process described differs from the ordinary basic process inasmuch as the converting is conducted in two stages: (1) desiliconising of the metal in an acid-lined converter; (2) the dephosphorising in a converter with a basic lining.

Production of Soft Steel in a New Type of Fixed Converter, by G. Hatton.—Description of a converter, which is claimed to have many advantages over the Bessemer converter.

T. Turner, Assoc.R.S.M. (Mason College), read a series of papers relating to the chemistry of iron and steel. The first was *On the Influence of re-melting on the Properties of Cast Iron.* No general rule can be laid down as to the influence of re-melting on the properties of cast iron; chemical changes take place during the melting: the amount of silicon is reduced whilst that of the sulphur is increased, and the effect of re-melting will be dependent upon the proportion of these elements present in the cast iron; a single melting will be sufficient to produce a deterioration in the qualities unless the silicon is in excess. A second paper was *On Silicon in Cast Iron.* Addition of silicon to hard white iron causes it to become soft and grey, and too much silicon makes the iron weak; by adding silicon in right proportion cast iron can be made of any desired degree of hardness. The third communication was one *On Silicon in Iron and Steel.* The author has succeeded in making a steel in which the carbon is replaced by silicon, which can be hardened like steel, is very tough when cold, and is well adapted for tools, but is difficult to work when hot. The author gave a short description of a method for estimating carbon in iron or steel.

A New Apparatus for Readily Determining the Calorimetric Value of Fuel and Organic Compounds, by W. Thomson, F.R.S.E.—The apparatus-described is an improved form of the calorimeter due to Lewis Thompson; the substance is burnt in a stream of oxygen instead of mixing it with potassium chlorate, as recommended by Thompson.

On some Decompositions of Benzoic Acid, by Prof. Odling, F.R.S.—When benzoic acid is heated in sealed tubes at about 260° with an aqueous solution of zinc chloride, it is decomposed, and yields chiefly benzene, together with a small quantity of diphenyl.

On the Methods of Chemical Fractionation and *The Fractionation of Yttria*, by W. Crookes, F.R.S.—In the Presidential address this subject was referred to, and in this communication a detailed account of the operation of "fractionation" is given. Fractionation, briefly, consists of first fixing upon some chemical reaction in which there is a likelihood of a difference existing in the behaviour of the elements under treatment; this is then performed in an incomplete manner, so that only a portion of the total bases present is separated, the object being to get part of the material in the insoluble and the rest in the soluble state. In the second communication the author described the fractionation of the earth yttria; in this case the fractionation has been greatly facilitated by the use of what the author styles the "radiant-matter test," which is dependent upon the spectra given by these earths when phosphoresced *in vacuo*. It would appear that there are certainly five, and probably eight, constituents into which yttrium may be split.

SECTION C—Geology

Geysers of the Rotorua District, North Island of New Zealand, by E. W. Bucke.—The author of this paper has recently returned from the Lake district of New Zealand, where he spent eighteen months, and had exceptional opportunities for making observations upon the volcanic phenomena of the district. The largest geyser in New Zealand, that of the White Terrace of Rotomahana, is now destroyed. The author determined by soundings the depth of the tubes of several geysers of this district, and in the case of an extinct one, that of Te Waro, he was let down the tube. He found that this tube, 13 feet from the surface, opened into a chamber 15 feet long, 8 feet broad, and 9 feet high, from one end of which chamber another tube led downwards to an undetermined depth. Living among the natives for months, and speaking their language, the author was convinced that by constant observations on the direction of the wind and the condition of the atmosphere they have learnt to prognosticate the movements in all these hot springs with wonderful accuracy. He was also able to prove that during the whole time of his residence in the district certain of the geysers were only in eruption when the wind blew from a particular quarter.

On the Glacial Erratics of Leicestershire and Warwickshire, by the Rev. W. Tuckwell.—Gives evidence of a south-western dispersion from Charnwood. In Stockton, a village midway between Leamington and Rugby, is boulder-clay containing abundance of Mount Sorrel granite, of so-called gneiss from Charnwood Forest, largely decomposed "pockets" of red sandstone, blocks of grey sandstone highly glaciated, Bunter pebbles, flints, Carboniferous limestone, Lias rock of a different texture from that native to the district. Lying loose in the village street, recently inclosed and inscribed, is a fine boulder from Mount Sorrel, glaciated, of nearly two tons weight. The author notes extraordinary profusion of Mount Sorrel erratics as far as Leicester; at Rothley, Thurcaston, Anstey; "Stone," or "Ston," is a suffix of nearly all the villages along the line. The largest boulder found in Leicestershire is near Humberston, estimated at twenty tons, partly embedded in boulder-clay which is filled with Bunter pebbles and rolled slate from Charnwood. Charnwood stones re-appear north and south of Coventry, at Eathorpe, 6 miles south-west of Coventry, at Stockton, completing evidence of a south-west stream from the Charnwood elevation throughout the two counties.

Manganese Mining in Merionethshire, by C. Le Neve Foster, D.Sc.—Manganese ore is now being worked in the Cambrian rocks at several places near Barmouth and Harlech. It occurs in the form of a bed varying from a few inches to 3 feet in thickness; the average thickness is 1 foot to 1½ foot. The undecomposed ore contains the manganese in the form of carbonate, with a small proportion of silicate; but at the outcrop it is changed into a hydrated black oxide. Some of the outcrops of the manganese bed are erroneously marked on the Geological Survey maps as mineral veins, though Sir Andrew Ramsay was of opinion that the deposits were not true lodes. Recent workings show plainly that the deposits are truly stratified beds, or possibly various outcrops of one and the same bed, extending over a considerable area. The ore contains from 20 to 35 per cent. of metallic manganese, and is despatched to Flintshire and Lancashire for the manufacture of ferro-manganese. The new Merionethshire mines are the first instance of workings for carbonate of manganese in the British Isles.

On the Silurian Rocks of North Wales, by Prof. T. McKenny Hughes, M.A., F.G.S.—The author begins by describing some sections in the Silurian rocks of North Wales, giving lists of fossils from the various horizons in each. He then, by means of these and by what he calls syntelism, that is, the occurrence of similar sequences of beds of the same characters, lithological or other, points out the corresponding parts of the various sections described. He then does the same for the Silurian of the eastern borders of the Lake district, and, having in this manner constructed a vertical section of each, compares the two districts and shows that there is an identical series in each, with all the important zones of one represented in the other, except that in the part of North Wales which he has worked out he has not yet detected beds as high as the newer part of the series in the Lake district.

Note to accompany a Series of Photographs prepared by Mr Josiah Martin, F.G.S., to illustrate the Scene of the recent Volcanic Eruption in New Zealand, by Prof. J. W. Judd, F.R.S., Pres.G.S.—Owing to the great enterprise and energy shown by

the managers of the local newspaper press in New Zealand very full and graphic accounts of the volcanic outburst of June 10 have already reached this country, and have been copied into the English papers. On the day of the eruption, Dr. James Hector, C.M.G., F.R.S., the Director of the Geological Survey of New Zealand, started for the locality, and his preliminary report, accompanied by maps and plans, has been published. Dr. Hector concludes that the eruption was a purely hydrothermal phenomenon on a gigantic scale, and that it was unaccompanied by any ejection of freshly molten lava either in the form of fragmental matter or of lava-streams. I have been favoured by Mr. J. E. Clark, F.G.S., with specimens of the material ejected during the eruption, and the microscopic examination of these entirely supports Dr. Hector's conclusions. It is a most unfortunate circumstance that the beautiful sinter-terraces of Rotomahana appear either to be blown to fragments or covered up under the enormous masses of mud thrown out in that locality. It luckily happens that a number of most excellent photographs, which illustrate very beautifully the characters of the wonderful sinter-formations, have been obtained. Mr. Josiah Martin, F.G.S., has especially devoted himself to the study of the district, and the series of photographs now exhibited constitute an invaluable record of the characters of the district destroyed by the eruption. These photographs show the points at which the volcanic cones were formed upon Tarawera, and the beautiful characters of the White Terrace (Te Terata), and of the Pink Terrace (Otukapuarangi), and the other wonders which surround the now destroyed Lake of Rotomahana. Now that the European settlement has been formed at Rotorua, a great service would be rendered to science if a meteorological station could be established there, and by simultaneous observations of the atmospheric conditions, and of the state of activity of the numerous hot springs, the question of the exact relations between these two sets of phenomena clearly established. When we remember that a fall of 1 inch in the barometer is equivalent to the removal of a load of nearly 90,000 tons over every square mile of surface, the effect produced on a district where steam issues whenever a walking-stick is thrust into the ground must be enormous. What is especially needed, however, by vulcanologists is a carefully tabulated series of records in the place of the general statements which have hitherto been published on this most important question.

The Relations of the Middle and Lower Devonian in West Somerset, by W. A. E. Ussher, F.G.S.—It has been suggested by Mr. Champernowne that the Foreland and Hangman grits might really be the same series, the appearance of conformable superposition of Lynton upon Foreland beds at Oare being ascribed to inversion. According to this view the downthrow of the fault at Oare would be to the north. The paper discusses this suggestion, its important bearing on the mapping of the area entitling it to consideration. The author advances five points in favour of the hypothesis, and three adverse to it, and gives some reasons why such difficulties as are experienced in drawing boundaries between the Foreland grits and Hangman beds might reasonably be expected to occur. The arguments against the identity of the Foreland and Hangman groups are too strong to be entertained without positive evidence in its favour. The author then briefly disposes of the possibility of the absence of the Lynton beds east of Luccot Hill being due to unconformable overlap of Hangman upon Foreland rocks, pointing out that if such were the case conglomerates ought to be found in the Hangman series, and the junction should also be marked by discordant relations of dip and strike.

A Scrobicularia Bed, containing Human Bones, at Newton-Abbot, Devonshire, by W. Pengelly, F.R.S., F.G.S., &c.—Description of a bed of fine sandy mud, 10 feet thick, crowded with *Scrobicularia piperata*, recently discovered near the head of the tidal estuary of the River Teign, Devonshire. Its top is 1 foot above the level of the highest spring tides in the estuary, and its bottom 3 feet above the low-water level. Ten feet down in the bed were found the following human bones: a skull, part of the left superior maxilla, containing two teeth, a right femur, and a right scapula—all believed to be of the age of the deposition of that part of the bed in which they lay. From the presence of the *Scrobicularia* there is apparently no doubt that since the era of deposition the district has been upheaved not less than 14 feet, nor more than 27 feet, and that the time was in all probability that of the elevation of the raised beach of Hope's Nose, about seven miles south-east of the *Scrobicularia* bed.

On a Deep Boring for Water in the New Red Marls (Keuper Marls) near Birmingham, by W. Jerome Harrison, F.G.S.—Around Birmingham the Keuper sandstone is divided from the Keuper marls by a line of fault running from north-east to south-west, roughly along the line of the River Rea. West of this fault the Keuper sandstone occupies the surface, and yields an enormous and unfailing supply of pure water, the Birmingham Corporation alone pumping about eight million gallons daily from three deep wells in this formation. East of the line of fault the Keuper red marls form an undulating band from five to twelve miles in width, the towns and villages on which depend wholly on surface waters, or shallow wells in surface gravels, for their water-supply. As the Keuper sandstone undoubtedly underlies the Keuper marls throughout the whole or the greater part of this tract of East Warwickshire, it is not surprising that attempts have recently been made to reach its locked-up waters by means of deep borings. Some seven or eight years ago the Birmingham Corporation bored in Small-heath Park (the southern suburb of Birmingham) to a depth of 440 feet, entirely in Keuper marls. The object of this paper is to describe a boring made during the present year at King's Heath, three miles south of Birmingham, at the brewery of Messrs. Bates, in search of water, which is now 667 feet deep, and still in marls and shales. From comparisons with the Keuper marls of Staffordshire, &c., the thickness of the Keuper marls at King's Heath can hardly be more than 700 feet. It is to be hoped that the Keuper sandstone will be reached almost immediately, and that its water-bearing properties will be such as to satisfy the requirements of the district.

On an Accurate and Rapid Method of Estimating the Silica in an Igneous Rock, by J. H. Player, F.G.S., F.C.S.—This paper describes a method of estimating the silica in igneous rocks by (1) fusing the finely ground rock with a flux prepared by mixing carbonates of potash and soda and nitrate of potash; (2) disintegrating the glass so obtained by the action of strong nitric acid; (3) driving off nitric acid at a temperature just below 250°, thus rendering all silica insoluble; (4) treating with hydrochloric acid, to leave the silica with some impurity, for weighing after calcination; (5) separating the impurity by means of ammonium fluoride and weighing it.

Notes on some Sections in the Arenig Series of North Wales and the Lake District, by Prof. T. McKenny Hughes, M.A., F.G.S.—In this paper the author describes a number of sections which cross the Arenig series in different parts of England and Wales, and endeavours to explain some apparent discrepancies in what is generally a remarkably constant set of beds. He starts with the Portmadoc section, where he considers that the chief differences of opinion have arisen from mistakes in the explanation of the geological structure of the district, especially from the wrong identification of some grit bands on opposite sides of important faults. Following the series to the north he shows that, although they vary in thickness, the principal zones are still represented near Carnarvon; and, discussing the question of the unconformity of these beds on the Lower Cambrian, he points out that the Lower Cambrian rocks are seen to vary so much both in character and thickness within short distances in the neighbourhood of the existing outcrop of the Archæan that any argument founded upon their thinning-out or their different texture must be received with distrust in an area where they are known to have been deposited on the flanks of mountain-ranges of pre-Cambrian age. He then describes some localities in the Lake district where the occurrence of the same zones has been determined, and points out the difficulty of getting rid of such great thicknesses of deposits of fine mud as would be implied in the usual interpretation of those areas.

On the Rocky Mountains, with Special Reference to that part of the Range between the 49th Parallel and Head-waters of the Red Deer River, by George M. Dawson, D.S., F.G.S., &c., Assistant Director, Geological Survey of Canada.—The term "Rocky Mountains" is frequently applied in a loose way to the whole mountainous belt which borders the west side of the North American continent. This mountainous belt is, however, preferably called the Cordillera region, and includes a great number of mountain systems or ranges, which on the 40th parallel have a breadth of not less than 700 miles. Nearly coincident with the 49th parallel, however, a change in the general character of the Cordillera region occurs. It becomes comparatively strict and narrow, and runs to the 56th parallel or beyond with an average width of about 400 miles only. This portion of the western mountain region comprises the greater

part of the province of British Columbia. It consists of four main ranges, or, more correctly, systems of mountains, each including a number of component ranges. These mountain systems are, from east to west:—(1) The Rocky Mountains proper. (2) Mountains which may be classed together as the Gold Ranges. (3) The system of the Coast Ranges of British Columbia, sometimes improperly named the Cascade Range. (4) A mountain system which in its unsubmerged portions constitutes Vancouver and the Queen Charlotte Islands. The present paper refers to the Rocky Mountains proper. This system, between the 49th and 53rd parallels, has an average width of about sixty miles, which, in the vicinity of the Peace River, on the 56th parallel, decreases to about forty miles. It is bounded to the east by the Great Plains, which break into a series of foot-hills along its base; to the west by a remarkably straight and definite valley occupied by portions of the Columbia, Kootanie, and other rivers. Since the early part of the century the trade of the fur companies has traversed this range, chiefly by the Athabasca and Peace River Passes, but till the explorations effected by the expedition under Capt. Palliser in 1858-59, nothing was known in detail of the structure of the range. During the progress of the railway explorations a number of passes were examined, and in 1883 and 1884 that part of the range between the 49th parallel and latitude 51° 30′ was explored and mapped in some detail in connection with the work of the Canadian Geological Survey by the author and his assistants. Access to this, the southern portion of the Rocky Mountains within Canadian territory, being now readily obtained by the railway, its mineral and other resources are receiving attention, while the magnificent alpine scenery which it affords is beginning to attract the attention of tourists and other travellers. The results of the reconnaissance work so far accomplished are here presented in the form of a preliminary map, accompanied by descriptions of routes and passes, and remarks on the main orographic features of the range.

Surface Subsidence caused by Lateral Coal-Mining, by Prof. W. Benton, A.R.S.M.—A paper showing that a large amount of coal is annually sacrificed in British mining for the lateral support of neighbouring and disinterested surface proprietaries; pointing out the results of this sacrifice, and enumerating the considerations which should govern the extent of this support.

A New Form of Clinometer, by John Hopkinson, F.L.S., F.G.S.—A "day and night" compass-card is set to true north over the compass-needle, which necessarily points to magnetic north. The diameter of the card is less than the length of the needle, so that the points of the needle project beyond the card, and the correction made is seen and can be adjusted when required. The same result would be attained by placing the card below the needle. The clinometer dip is as usual below the magnetic needle, and can be easily seen outside the compass-card. The advantage of being able to take the amount and direction of the dip of strata with a single instrument without loss of time and liability to error in making the correction for magnetic deviation, and at the same time having the points of the compass exposed for more minute observations if required, must be obvious. The present deviation is 17° 50′ W. of N., and it is lessening. The instrument was exhibited.

Statistics of the Production and Value of Coal Raised within the British Empire, by Richard Meade, Mining Record Office.—This paper, prepared at the request of the Committee to accompany other papers on the Colonial coal resources, gave particulars of the quantity and value of coal raised for several years past, in many cases for ten years. We give here only the amount and value quoted for the latest year in each case:—

	Date	Quantity Tons	Value £
Queensland	1885 ...	209,500 ...	not given
New Zealand ...	1883 ...	408,831 ...	360,622
Victoria	1884 ...	not given ...	3,280
Natal	1883 ...	5,000 ...	1,000
India	1883 ...	1,315,976 ...	657,988
Cape of Good Hope	1884 ...	9,000 ...	7,250
Tasmania	1884 ...	7,194 ...	6,381
Canada	1884 ...	1,876,643 ...	619,336
United Kingdom	1885 ...	159,351,418 ...	41,139,408

On Canadian Examples of Supposed Fossil Algæ, by Sir William Dawson, LL.D., F.R.S.—Markings of various kinds on the surfaces of stratified rocks have been loosely referred to Algæ or Fucoids under a great variety of names; and when recently the attempt was made in Europe more critically to define and classify these objects, a great divergence of opinion developed itself, of which the recent memoirs of Nathorst, Williamson, Saporta, and Delgado may be taken as examples. The author, acting on a suggestion of Sir R. Owen, was enabled, in 1862 and 1864, by the study of the footprints of the recent *Limulus polyphemus*, to show that not merely the impressions known as *Protichnites* and *Climactichnites*, but also the supposed Fucoids of the genera *Rusophycus*, *Arthrophycus*, and *Cruziana* are really tracks of Crustacea, and not improbably of Trilobites and Limuloids ("On Footprints of Limulus," *Canadian Naturalist*, 1862; "On the Fossils of the Genus *Rusophycus*," *ibid.* 1864). He had subsequently applied similar explanations to a variety of other impressions found on Palæozoic rocks ("On Footprints and Impressions of Aquatic Animals," *American Journal of Science*). The object of the present paper was to illustrate, by a number of additional examples, the same conclusions, and especially to support the recent results of Nathorst and Williamson. *Rusichnites*, *Arthrichnites*, *Chrossochorda*, and *Cruziana*, with other forms of so-called *Bilobites*, are closely allied to each other, and are explicable by reference to the impressions left by the swimming and walking feet of Limulus, and by the burrows of that animal. They pass into *Protichnites* by such forms as the *P. Davisii* of Williamson, and *Saerichnites* of Billings, and *Diplichnites* of the author. They are connected with the worm tracks of the genus *Nereites* by specimens of *Arthrichnites*, in which the central furrow becomes obsolete, and by the genus *Gyrichnites* of Whiteaves (*Transactions* of the Royal Society of Canada, 1883). The tuberculated impressions known as *Phymatoderma* and *Caulerpites* may, as Zeiller has shown, be made by the burrowing of the mole-cricket, and fine examples occurring in the Clinton formation of Canada are probably the work of Crustacea. It is probable, however, that some of the later forms referred to these genera are really Algæ related to *Caulerpa*, or even branches of Conifers of the genus *Brachyphyllum*. *Nereites* and *Planulites* are tracks and burrows of worms, with or without marks of setæ, and some of the markings referred to *Palæochorda*, *Palæophycus*, and *Scolithus* have their places here. Many examples highly illustrative of the manner of formation of these impressions are afforded by Canadian rocks. Branching forms referred to *Licrophycus* of Billings, and some of those referred to *Buthotrephis*, Hall, as well as radiating markings referable to *Scotolithus*, *Gyrophyllites*, and *Asterophycus* are explained by the branching burrows of worms illustrated by Nathorst and the author. *Astropolithon*, of the Canadian Cambrian, seems to be something organic, but of what nature is uncertain. *Rhabdichnites* and *Eophyton* belong to impressions explicable by the trails of drifting sea-weeds, the tail-markings of Crustacea, and the ruts ploughed by bivalve mollusks. *Dendrophycus*, *Dictyolites*, some species of *Delesserites*, *Aristophycus*, and other branching and frond-like forms, were shown to be referable to rill-marks, of which many fine forms occur in the Carboniferous of Nova Scotia, and also on the recent mud-flats of the Bay of Fundy. The genus *Spirophyton*, properly so called, is certainly of vegetable origin, but many markings of water-action, fin-marks, &c., have been confounded with these so called "Canda-galli Fucoids." On the other hand, some species of *Palæophycus*, *Buthotrephis*, and *Sphenothallus* were shown to be true Algæ, by their forms and the evidence of organic matter, and *Haliserites*, *Barrandeina*, and *Nematophycus* were shown to include plants of much higher organisation than the Algæ. With reference to the latter, it was held that the form to which the name *Prototaxites* had been given was really a land plant growing on the borders of the sea, and producing seeds fitted for flotation. On the other hand, certain forms to which he had given the name *Nematoxylon* were allied to Algæ in their structure, and may have been of aquatic habit; very perfectly preserved specimens of these last had been recently found, and had thrown new light on their structure. The author proposed to apply to all these problematical plants, having a tissue of vertical and horizontal tubes, the general name *Nematophyteæ* or *Nematophyton*. The paper referred to the history of opinion on these objects and the bibliography of the subject; but this, as well as detailed descriptions, are omitted in this abstract.

Notes on some of the Problems now being Investigated by the Officers of the Geological Survey in the North of Ireland, chiefly in Co. Donegal, by Prof. E. Hull, LL.D., F.R.S.—The author stated that the investigations of the Survey were confined to the counties of Antrim and Donegal, and, restricting his observa-

tions to the latter, he said the problem was whether or not there were two great series of metamorphic rocks unconformable to each other, the older referable to the Archæan age, the newer to the Lower Silurian. Some reference was made to the great faults and foldings of these beds, which were stated to range generally in N.N.E. and S.S.W. lines. It was considered that the granites might belong to at least two periods—the intrusive being distinct both in age and structure from the metamorphic granite and gneiss. Other points noticed were the occurrence of numerous basaltic dykes, probably of Tertiary age, traversing the gneissose rocks; and marginal representatives of the Lower Carboniferous period.

On the Classification of the Carboniferous Limestone Series; Northumbrian Type, by Hugh Miller, F.R.S.E., F.G.S., of H.M. Geological Survey.—The object of this paper was to show that the classification proposed twenty years back by G. Tate of Alnwick is still sufficient, not only for North Northumberland, where Tate established it, but also for the south of the county. Prof. Lebour has proposed another classification on the assumption that Tate's divisions either do not exist in Nature, or do not persist throughout the county. Tate's classification, amplified in some not very important details, and adapted to the work of the Geological Survey, is as follows:—

		Feet
Upper Limestone Series	*Felltop or Upper Calcareous Division:—From the Millstone Grit to the zone of the Great Limestone.* Sandstones and shales; one or more beds of marine limestone, including the Felltop Limestone; some coals	350-1200
	Calcareous Division:—From the great Limestone to the bottom of the Dun or Redesdale Limestone. Many beds of good marine limestone; sandstones and shales; coals	1300-2500
Lower Limestone Series	*Carbonaceous Division (Scremerston Beds of North Northumberland:—From the Dun or Redesdale Limestone to Tate's "Tuedian Grits."* Strata prevalently carbonaceous; limestones chiefly thin, many of them containing vegetable matter; coals	800-2500
	Tuedian Division:—Upper Tuedian or Fell Sandstone Group, the "Tuedian Grits" of Tate:—From the Carbonaceous Group to the Cement-Limestones. Great belt of massive grits (Tweedmouth, Chillingham, the Simonside, and Harbottle Hills, the Peel, and Bewcastle Fells). Shales greenish and reddish as well as carbonaceous gray; coals rare, thin, or absent ...	500-1600
	Lower Tuedian or Cement-Limestone Group:—From the base of the Grits downwards. Cement-stone bands passing into limestones (Rothbury, Bewcastle); coals very rare; generally some coloration of the shales and sandstones	500-1500
	Basement Conglomerates (Upper Old Red Sandstone); local	—

Notes on the Crystalline Schists of Ireland, by Ch. Callaway, D.Sc., M.A., F.G.S.—The author gives a summary of results obtained by a preliminary survey of the principal areas of Irish metamorphic rocks in Donegal, Connemara, and the south-eastern corner of the county of Wexford. In each of these areas the following facts were observed:—(*a*) A series of hypometamorphic rocks, consisting typically of fine-grained schists, altered grits, and quartzites. A clastic structure is more or less distinct in the three areas, but is least evident in Connemara. (*b*) A group of highly crystalline schists, displaying no trace of an original sedimentary origin, dipping as if it passed below the hypometamorphic rocks. At Wexford there are true gneisses. In Connemara the rocks are less feldspathic, the chief types being quartzose gneiss, quartz-schist, mica-schist, hornblende-schist, quartzite, and crystalline limestone. This description will also apply to Donegal. (*c*) Granite, underlying (*b*), and in Connemara and Donegal clearly intrusive. The author urges that this analogy is not due to the metamorphic action of the granite; for—(1) The mineral characters apparent in the schists adjacent to the granite are uniformly distributed through the lower series from bottom to top. (2) The evidence collected is hostile to the view that this lower series ever graduates into the upper. It is concluded that the balance of proof is in favour of the Archæan age of the bulk of the Irish schists. (1) In the Wexford district the schists are thrown against Cambrian and Ordovician rocks by faults, and do not pass into them in the localities alleged by the Irish Survey. (2) In Connemara conglomerates of Llandovery age contain large rounded fragments, not only of the older schistose series, but also of its intrusive igneous rocks. (3) In the Ulster region the metamorphic area is separated from the Ordovician rocks of Pomeroy by a ridge of granite and diorite three miles in breadth. The lithological analogies between the Irish schists and the Archæan rocks of Anglesey and other British metamorphic districts are also of weight in the argument.

SOCIETIES AND ACADEMIES

Edinburgh

Royal Society, July 19.—The sense of taste, by John B. Haycraft. Sensation or feeling is a result of the operations of the external world upon our sentient bodies. A vibration of light, a sonorous wave, a molecule of sugar or of musk stimulates the appropriate nerve through the mediation of a little sensitive cellule in the eye, the ear, the tongue, or the nose. A motion called a *nerve motion* is then set up, passes to the brain, and if this organ is in a state of activity we are conscious of a feeling or sensation. In the case of sound and light the character of the vibration determines the quality of the sensation produced. Thus, a certain complex vibration of light produces a sensation we call crimson, a certain complex vibration of sound we recognise as coming from a violin-string. Motion is thus transmitted into a nerve motion or impulse, which gives rise to a sensation. Of the thousand qualities of sensation all have a counterpart in the thousand variations of motion outside the body. The physiologist knows little more about the production of the sense of taste than those facts which are the intellectual property of every one. The object of the author of the paper of which this is a short abstract is to show that taste in its method of production is precisely analogous to sight and hearing. The truth of this is indicated by the striking similarity in structure between the end-organs of all the special senses, which are all developed from primitive ectodermic cells, of much simpler form. Spectroscopic investigation has demonstrated, too, that the sapid and odorous molecules vibrate constantly and in a manner characteristic of each substance. We have, then, in the case of taste (and it is hoped subsequently to demonstrate this in the case of smell as well), vibrating matter and a sensitive end-organ, conditions analogous with those present in the other senses. If it can be shown that substances vibrating in the same manner produce the same taste, the analogy will be complete. It has been found by Newlands and others that if the elements be arranged in a series, starting with that metal which has the lowest, and passing up to that which has the highest, atomic weight, a periodic recurrence of chemical and physical properties is observed. Thus lithium, the second in the series, is similar to sodium, the ninth, and potassium, the sixteenth, and so on. This is called the periodic law. The author finds that there is also a periodicity as regards taste production. Thus the chlorides or sulphates of a series of similar elements—called a group of elements by Mendelejeff—have similar tastes. It is curious, however, that the taste changes slightly but uniformly as we pass to the higher members of a group. Thus the chlorides of lithium and sodium are salt, but as you pass to the higher members of the group the taste becomes more saline and very slightly bitter. Now Prof. Carnelley has recently discovered that compounds containing elements of the same group have similar colours, the colour changing, however, uniformly—passing to the red end of the spectrum—as we reach the higher members of a group. Colour is periodic. But this indicates that the elements of the same group are vibrating in a similar way. If the lower member be yellow from absorption of the blue, the next one will have vibrations of nearly the same pitch, being in reality at a somewhat slower rate of vibration, and absorbing rays nearer the red end. Here, then, is the analogy sought for. A group of salts of similar chemical properties have their molecules in a

similar vibrating condition, giving rise to similar colours and similar tastes. A study of the carbon compounds yields as conclusive evidence. The alcohol bodies, such as mannite, grape-sugar, glycerine, glycol, are sweet. They possess a certain common molecular structure and a compound radical, $CH_2.OH$. Associated with this radical is the taste called sweet, just as are associated with it many chemical and physical properties. Common alcohol is tasteless, but it is monatomic, all the polyatomic alcohols having a sweet taste. The organic acids, too, have a radical, CO.OH, with which seems to be associated their acid properties and the power of producing a special taste. Now it is certain that compound radicals, like elementary substances, vibrate in a definite way, however they are combined. A coloured acid like chromic and picric acid forms a class of coloured salts. Ammonia viewed in quantity shows characteristic absorption-bands; replace an atom of hydrogen by ethyl or methyl, and the same bands are to be observed, shifted, however, slightly towards the red end of the spectrum. We see, then, in the carbon compound the radical vibrates, modifies light passing through it in a definite way, and affects the sensorium by causing the production of a definite sensation of colour. So too it can produce a definite taste sensation. I do not hazard an opinion as to how the molecule stimulates the end-organs in the tongue. Too little is known about the stimulation of the retina by light. Whether or not in both cases it is mechanical, one cannot say. As to its being chemical action, it may well be asked, What is this? Chemical action itself may perhaps be most satisfactorily interpreted by the use of a mechanical hypothesis. Much has yet to be discovered as to the exact relationship between vibration and taste sensation. That this relationship exists, is all the author wishes to prove. When spectroscopic investigation of the invisible spectrum is more advanced, what Helmholtz has done for sound may also be done for taste, and we may know the exact vibrational counterpart of a taste quality as we know it already of the sound of a violin-string.

PARIS

Academy of Sciences, September 13.—M. Émile Blanchard in the chair.—Experiments on the electrical conductibility of gases and vapours, by M Jean Luvini. A series of experiments are described, which have led the author to the general conclusion that, under all pressures and at all temperatures, gases and vapours are perfect insulators, and that they cannot be electrified by friction either with themselves or with solid or liquid bodies. Crucial tests were applied to air saturated with the vapour of water at temperatures ranging from 16° to 100° C.; to hydrogen and carbonic acid not dried, but just as they left the bath generating them; to the vapour of mercury at 100° C.; the vapours of sal ammoniac; air heated by live embers or the flame of a candle; the fumes of sugar, camomile, incense, &c., none of which vapours gave the least indication of conductibility. Hence to suppose, as is generally done, that very rarefied gases, or gases at very high temperatures, are conductors, is a mistake due to confusion between resistance to disruptive and conductive discharges. Thus Masson has shown that at like potential the distance of the disruptive discharge in the air is twelve or thirteen times greater than in water, which simply means that the resistance of water to the disruptive discharge is greater than that of air, not that air is a better conductor than water. Henceforth physicists will have to reject all theories regarding the electricity of machines, the air, or clouds, in which moist air is assumed to be a conductor, or in which gases and vapours are supposed capable of being electrified by friction.—Quantitative analysis of the dry extract of wines, by M. E. Bouilhon. In order to shorten the ordinary tedious process, some chemists separate the liquids by means of porous bodies increasing the surface of evaporation. But this method leads to fallacious results, numerous experiments showing that all increase of the surface lowers the weight of the residuum to a very considerable extent, in consequence of the evaporation of a portion of the glycerine. Thus a litre of claret yielded 22·4, 22·0, and 21·2 grammes of sediment according to the various forms and sizes of the vessels employed in the process.—On *Fecampia erythrocephala*, a new species of Rhabdocœle, parasitic and nidulating, by M. A. Giard. This species, which is very common on the coasts of Fécamp and Yport, is shown to differ considerably from Graffilla and the different genera of Rhabdocœle hitherto described. It appears greatly to resemble a parasite discovered by Lang in the foot of *Tethys fimbriata*, and a more complete study of this Mediterranean type will no doubt show that, like the parasite here described, it also secretes a cocoon.—Researches on the circulatory apparatus of the Ophiures, by M. R. Kœhler. The circulatory system of these organisms, as here described, appears to be very analogous to that of the Echinidæ, as already revealed by previous investigations of the author and M. Prouho. Both groups present the same structure of the madreporic gland, the same relations of this gland, on the one hand with the periphery, on the other with a peribuccal ring; two peribuccal rings throwing off two branches in the same directions; lastly, the absence of aboral circle.—On the heart, digestive tube, and reproductive apparatus of *Amaræcium torquatum* (a Compound Ascidian), by M. Charles Maurice. In this paper the author determines the true physiological functions of some of the organs already observed by Seeliger, Von Drasche, and Della Valle in other species of Ascidians.—On the annual movement of the barometer in European Russia, by General Alexis de Tillo. While the yearly oscillations of the barometer in Siberia may be figured by a curve of somewhat simple type, those of European Russia are shown to be of a much more complicated character. From the numerous records published by the St. Petersburg Central Physical Observatory, the author has deduced the mean monthly readings for eighty meteorological stations in this region, and these data have enabled him to determine the mean type of the annual barometrical curve for the centre of European Russia. As it advances eastward in the direction of Siberia and Central Asia, this curve loses its secondary maxima and minima, while on the other hand its amplitude increases gradually.

OUR GUNS

WHEN a careful engineer sets about designing a structure, he first determines the strain which the several parts of it will have to withstand; he then selects his material and proportions it so that it will be able to carry the strains safely; in determining the margin which should be allowed he uses judgment based upon his own experience or that of others who have designed similar structures; and if the strains be difficult to determine, or if they be of the nature of severe and sudden shocks and complicated cross strains he increases his margin in proportion. Experience has shown, for example, that wrought iron in the form of a railway bridge may be worked safely at a load equal to one-fourth of that which will break it down, a cast-iron bridge to one-sixth. The builder of a steam-engine rarely loads those parts of his machinery which have to endure sudden and reverse strains to more than one-eighth or one-tenth of their ultimate strength. If his structure fail, the first thing the engineer does is to re-calculate his strains and the dimensions he has given to the various parts, and if these should prove correct he seeks for the cause of failure in unlooked-for defects in his material; and if failure in the same class of structure, of various sizes, recur repeatedly in the same place, he comes to the conclusion, either that he has under-estimated the strains, or that the margin of safety which he has allowed is not sufficient. An engineer accustomed to act in this manner must look with dismay upon the report of the Committee appointed to examine into the cause of the failure of the 12-inch gun of the *Collingwood*, and of other guns of similar construction It is possible, of course, that the Committee have been able to calculate the strains which tend to destroy the guns, and have satisfied themselves that sufficient metal has been provided for the purpose; but, if so, it is much to be regretted that they have not seen fit to make the results of their investigations public, because it would have been instructive to know how the stresses are arrived at and what margin of safety is considered sufficient for a gun. When Colonel Maitland read his paper on our new guns at the United Service Institution in the middle of 1884, the strains certainly were not known to the Ordnance Committee, because the pressure curves, purporting to represent one-fourth of the bursting pressure of the guns, and which were given on the official drawings, were incompetent to account even for the muzzle energy which the shot was supposed to possess, and consequently provided nothing whatever for other important work which has to be performed during the discharge. This fact was pointed out by the *Engineer* early in 1885, in an article commenting on one of the Howard Lectures which had just been delivered at the Society of Arts, and the weak point in our guns was actually indicated before any failures had taken place!

How much has the knowledge of the Ordnance Committee advanced in the meantime, and is four still considered a sufficient factor of safety? Any careful engineer who reflects on the strains a gun is subjected to would certainly class it among steam-engines, subject to the roughest work, and not to the class of railway bridges, which have well-defined and simple strains to stand. What takes place when a gun is discharged? First, there is the direct pressure of the gases, which is still very imperfectly known. Next, this pressure travels along the bore at a very rapid rate, producing a shearing strain between the material in advance of, and in rear of the base of the shot, and this strain is intensified at each point where a sudden change of thickness takes place. Thirdly, there is the reaction to the force producing rotation of the shot, which tends to twist the barrel. Fourthly, there are the strains produced by the momentary presence of a white-hot body pressing against the walls of the bore with a pressure ranging from 25 tons to 1 ton per square inch; and, lastly, there is the longitudinal strain representing the reaction between the pressure on the base of the bore and the inertia of the gun itself. What engineer would dream of counteracting such strains as these with a less margin than eight or ten, if he were perfectly unfettered, and if he were certain of the manner in which the strains were transmitted through the metal of the gun; but even on this point there are grave doubts, for it seems almost certain that the strains travel as pulses or vibrations, in a manner which sets at defiance all ordinary modes of calculation. No engineer would be surprised if guns, with a factor of safety of only four, burst frequently.

But it will, no doubt, be argued that guns of the strength suggested would be impracticable. We do not hold that opinion, because weight in a gun, even for naval purposes, is not objectionable, since the force of recoil diminishes with the increase of weight, and the metal appropriated to the gun would be saved in the carriage and structure of the ship; while, for land service, weight can be no objection whatever. The Committee make no allusion to a necessity of keeping down the weight of guns, hence it must be supposed that they would not sacrifice safety to this end, although it is well known that there is a kind of race among gun-makers to produce the greatest amount of shot-energy per ton of gun. It seems to us, therefore, most unfair that the whole blame of our failures is to rest on the Royal Gun Factory, that is, on the quality of material and on the manufacture, when it is certain that the faults are faults of design—a want of sufficient metal—a view which the Committee adopt by their acts, though not by their words; for they are adding largely to the weight of the guns in the very parts which experience and the investigations of outsiders have proved to be deficient in strength.

But although the Ordnance Committee are reticent as to the scientific views which they hold respecting the structure of guns, they have a way of taking the public into their confidence, through the instrumentality of a lecture delivered by one of their body, whose talents as an agreeable expounder of popular science are well known, and they show much wisdom in making these manifestations take the form of lectures instead of papers read before scientific Societies. The advantage of a lecture is that no awkward questions can be asked, and no fallacies or errors pointed out. Thus, when the *Thunderer's* gun burst, Sir Frederick Bramwell delivered a very pleasant lecture at the Royal Institution, and the other day the same gentleman selected the subject of our guns as the

theme of his address to the Midland Institute at Birmingham, and, we have no doubt, charmed his audience with his manner and ready wit. But what is there in either of the lectures just mentioned that throws the slightest light on the real difficulties of the subject? Why was not Sir F. Bramwell moved to read a paper at the meeting of the British Association which took place a few weeks ago in the very building in which he addressed the Midland Institute? Had such a paper been read, a most interesting and animated discussion would have arisen, and the nation would have had the advantage of learning the opinions of men who have devoted their lives to working out the problems connected with the theory as well as the practice of the construction of ordnance. We are driven to the conclusion that the Ordnance Committee considered that such a course would have been dangerous to their self-respect; the deplorable ignorance which characterises all attempts at working out difficult questions by Committees would have been too glaringly exposed; it was much safer not to subject themselves to cross-examination.

If we are wrong, if the Committee have complete answers to the questions raised, it is open to them to convince the nation of the fact, because the sessions of the Institution of Civil Engineers will very soon commence, and some member of the Ordnance Committee should be deputed to read, not a popular lecture, but a serious paper that will demonstrate to a roomful of practical engineers that our guns have been constructed according to the rules which guide engineers in their ordinary work, and that yet they have failed. We have small hopes that the challenge will be accepted.

THE MATHEMATICAL AND PHYSICAL SCIENCES

Histoire des Sciences Mathématiques et Physiques. Par M. Maximilien Marie. Tomes I.-IX. (Paris: Gauthier-Villars, 1883-86.)

M. MARIE'S great work advances rapidly towards completion. The first three volumes appeared in 1883; the concluding three are in the press; we have now before us nine volumes, bringing down the narrative from the time of Thales to the time of Laplace. The undertaking is a vast one; and we are not surprised to hear that it has cost forty years of preparation. The learned world is to be congratulated that it has fallen into such able hands. M. Marie combines, in a rare degree, scientific with literary qualifications. A certain grace and poignancy of style set off his wide erudition and practical acquaintance with methods of teaching. He can be vivacious even over processes of integration. The accumulated mass of his materials nowhere hinders the lightness of his tread. Keen touches of sarcasm enliven his most abstruse expositions, and agreeably remind his readers that a sense of humour may subsist concurrently with a thorough mastery of the higher analysis.

He has accordingly produced a book which, with these merits and some corresponding defects, only a Frenchman could have written—one eminently interesting and original, at once lively and profound, instructive throughout if occasionally one-sided, frankly displaying the prepossessions of its author, and not unfrequently—as we shall presently show—his heedlessness of historical and biographical accuracy. Its characteristic merit consists in the lucid interpretations contained in it of the older methods of mathematical research. The works of ancient and mediæval geometers are analysed, not barely in the view of exhibiting the results attained by them, but with the further purpose, most completely realised, of rendering their various artifices and modes of working intelligible to the least skilled in the archæology of mathematics. M. Marie's is indeed in no sense a book for beginners. It presupposes a considerable acquaintance with the most recent developments of analysis. The reader thus provided may, however, follow with ease and pleasure the steps by which earlier inquirers advanced; he may enter into their conceptions, place himself at their precise point of view, and while marvelling at the ingenuity which carried them so far, study the limitations of thought which hindered them from proceeding any farther. He may learn how the singular deficiency in the idea of abstract number which hampered the workings of such luminous and powerful minds as those of Archimedes, Apollonius, and Euclid, was supplied from the far East; how Hindu algebra and arithmetic formed the complement of Greek geometry; how both were transmitted through Arabic channels to Italy, and together constituted the starting-point of modern discoveries. Nor is it less curious to watch the gradual emergence of ideas big with the progress of the future, such as those of negative and imaginary, or infinitely small quantities; how they presented themselves with hesitation, and were at first shunned and distrusted; how they grew bolder and insisted on recognition; how their tentative and partial treatment became widened and generalised until they finally developed the whole extent of their capabilities.

It is well known that Archimedes gave the first approximation to the value of π; but the occasion and significance of the step are often lost sight of. It marked, with the almost simultaneous attempt of Aristarchus of Samos to measure the relative distances from the earth of the sun and moon, the introduction of numerical calculation into theoretical researches (Marie, t. i. p. 59). The novel effort was prompted, in each case, by the interest of a special problem. Archimedes, naïvely enough, sought to prove that the idea of infinity had its root in enumerative impotence, and could be abolished by expanding the resources of arithmetic. He exemplified his contention by computing the number of grains of sand contained in a sphere with the interval from earth to sun for its radius. But a preliminary valuation of the ratio between the circumference of a circle and its diameter was indispensable; and the tract on the "Dimension of the Circle" was accordingly, in M. Marie's plausible view, written as a kind of preface to the "Arenarius." Incidentally to the calculations in the latter treatise, he perfected the Greek system of numeration, and foreshadowed the principle of logarithms.

M. Marie has ventured a kind of restoration of the "algebra" of Archimedes (t. i. p. 262). His remarks on this disputed subject are of great interest. He holds it impossible that his inventions should have been reached by the arduous path of his demonstrations; and ascribes to him, accordingly, the possession of a compendious method of reasoning founded on the transformation of

ratios, conducting easily to results otherwise unattainable even by his transcendent genius. The secrecy observed regarding it may have been due, in part to the difficulty of setting it forth in the absence of a suitable algorithm, in part to the conventional prevalence of the synthetic mode of exposition. The art was doubtless held in common with Apollonius, and other geometers of the time; but was treated as a mere rude tool, not worth the labour of bringing to a higher perfection. Had this early analysis been independently cultivated, and set free from its servitude to geometry, the "method of exhaustions" must, by its aid, in our author's opinion, have given birth to the Calculus eighteen hundred years before Cavalieri thought of his "infinitesimals."

The work before us aims, above all, at developing, as a coherent whole, the logical sequence of ideas. It would be unfair to say that this aim has been missed; yet we cannot help thinking that it might have been more perfectly attained. A vivid light, it is true, is frequently thrown upon obscure passages of research, and the filiation and significance of discoveries are, here and there, brought out with uncommon sagacity. Nevertheless, there is something wanting which M. Marie could easily have supplied.

A somewhat fragmentary plan has governed the composition of the book. The twenty-four centuries embraced by it are divided into sixteen periods of very unequal length, treated each in a section apart, consisting of a prefatory sketch of the progress accomplished during its course, followed by a series of biographies of those who contributed towards it, arranged in strict chronological order. Chemists and mathematicians, astronomers and botanists, mechanicians and physiologists, are thus placed side by side, with no closer tie of connection than the successive occurrence of the years of their birth. We have no sooner done with Lagrange's Calculus of Functions than we are confronted with Watt's transformation of Newcomen's steam-engine; the convulsions of Galvani's memorable frog succeed; and we pass thence to Parmentier's triumphant growth of potatoes on the plain of the Sablons,—all subjects of great interest, and treated with singular charm. Yet their variety, if it form, in a certain sense, an attraction, demands a stronger bond of unity than is here afforded. The true historical element, in short, is deficient. Nor is the want satisfactorily supplied by M. Marie's sixteen prefaces. We should be sorry to lose them; but they do not suffice. The absence of a connected narrative is still sensibly felt. Even if its design had otherwise remained unchanged, the book might at least have been provided with a general introduction, delineating and characterising the course of events to be detailed, pointing out the confluence, at epochs of discovery, of various and distant streams of thought, and presenting, in one luminous view, the progress in exact knowledge made by our race from the first dawn of civilisation until now. Perhaps it may not even yet be too late to add to a most valuable work a supplementary volume which would go far towards rendering it complete.

In another direction, M. Marie has perhaps unduly extended the scope of his enterprise. To have treated adequately the history of *all* the sciences, natural as well as mathematical, would have demanded, not a dozen, but fifty volumes. Yet all are nominally included in his scheme, while, in point of fact, those branches of knowledge remote from his principal theme receive only the casual attention of some stray jottings, with biographical notices of their leading promoters.

His choice of representative names, too, is open to criticism. Among omissions, that of Adelard of Bath, the first translator of the "Elements of Euclid" from the Arabic, is very remarkable. He was one of the most effective popularisers of Arab science in the thirteenth century, and played no unimportant part in the revival of mathematical learning. Yet he is not only ignored by M. Marie, but his version of Euclid is handed over to Campanus of Novara, with whose commentary it was published at Venice in 1482, and who has in consequence frequently gained the credit of its execution.

Nor should the unfortunate Cecco d'Ascoli have been altogether forgotten. His "Acerba," if not all that it has been claimed to be, contains many striking intuitions of natural truths. M. Marie, however, takes little interest in the premonitory symptoms of discovery; and the rage for unearthing its obscure anticipations has possibly been carried a little too far. We miss, further, the name of Giambattista della Porta, the *effective* inventor of the camera obscura, whose "Magia Naturalis" was of European fame and influence. And William Cullen, the founder of rational chemistry in Great Britain, was at least as well worthy of notice as Kunckel, known in connection with the manufactures of ruby glass and of phosphorus, to whom just three times the space is allotted as to Black, the discoverer of "fixed air," and of "latent heat."

A crowd of superfluous names, on the other hand, might be cited. It seems ungracious to object to the presence of a sketch so interesting in itself as that of the career of Ambroise Paré; yet it is not easy to see what the treatment of gunshot wounds has to do with the history of mathematical or physical science. Equally outside the proper scope of its cognisance are Henkel's improvement of Dresden china, Bosc d'Antic's contributions to the art of glass-making, Perronnet's bridges, Trudaine's "superb" highways, and Vaucanson's automata. If these give a valid title to admittance, why exclude Hargraves, Arkwright, Smeaton, MacAdam, and a host besides? Why should the spinning-jenny be passed over in silence, when Loriot's ribbon-loom comes in for honourable mention? In truth, however, industrial and mechanical inventions belong elsewhere.

It remains that we should justify our hint that M. Marie's facts and dates occasionally stand in need of revision. A perusal of Prowe's "Life of Copernicus" would have obviated several inaccuracies in his brief account of the reformer of astronomy. The intention of Copernicus to embrace the ecclesiastical state was not superseded, even momentarily, by his journey to Italy; on the contrary, he received his appointment as Canon of Frauenburg in 1497, shortly after he had entered the University—not of Padua, as stated by M. Marie, but of Bologna. Nor was he ordained a priest at Cracow in 1501. He took minor orders on entering the Chapter, but never became a priest; and his sojourn in Italy was unbroken between 1501 and 1505. Moreover, his doctoral degree (not in medicine, but in canon law)

was conferred at Ferrara, May 31, 1503. He sought no diploma at Padua, though he studied medicine there during the four years of his *second* stay in Italy. The assertion that at the age of twenty-seven he was summoned to profess mathematics at Rome is inexact. Uninvited, so far as is known, he repaired thither with his brother early in the year of jubilee (1500); and delivered unofficially some brilliantly-attended lectures during the ensuing winter. Finally, he settled down to his life's work at Frauenburg, not in 1510, but in 1512.

One rubs one's eyes in amazement to find Basil Montagu's discredited and superseded edition quoted as the best and completest of Bacon's Works. Is it really possible that the news of the late Mr. Spedding's labours has not yet reached Chantilly? It would appear not; for his name is unmentioned by M. Marie, who equally overlooks Mr. Fowler's instructive edition of the "Novum Organum."

In the date assigned for Robert Hooke's death, he copies an error of Poggendorff's, who states that he died at the age of eighty-seven, whereas he did not live to complete his sixty-eighth year. The substitution of 1722 for 1703 is of more than simply formal importance, since the publication of Newton's "Optics" and his acceptance of the Presidentship of the Royal Society, both depended upon the event thus post-dated. Newton loathed controversies, although drawn into many. But while Hooke lived, they could only be avoided by self-effacement; and this was accordingly the policy adopted, as far as possible, by his great rival.

M. Marie makes no secret of his aversion to the sour little professor of Gresham College; and it is too true that his character repels sympathy, while his achievements were not of the dazzling sort to blind men to his failings. Still, his claim to due recognition remains intact, although ignored by our author, who states openly that only Poggendorff's eulogies, by "forcing his hand," frustrated his intention of punishing his egotism with neglect. Yet Hooke, by Newton's express admission, discovered independently the law of inverse squares, and it is not too much to say that, but for his incitements, Newton would not have undertaken the investigation which led to his immortal discoveries.

M. Marie's grudge against Hooke does not seriously detract from the value of his work; but it is otherwise with his ill-will towards Newton. Not only is he avowedly the partisan of Leibnitz in the never-ending debate concerning the invention of the Calculus; but his dislike (not wholly unjustifiable) to Newton's conduct in the matter extends to all the processes of his mind. He compels himself, it is true, to utter a few obligatory words in acknowledgment of the greatness of his work; but its entire significance seems to escape him. His readers are only quite casually reminded that the discovery of the system of the world was of greater moment in the history of science than the solution of the problems of the brachystochrone, or of the centre of oscillation.

We are told by M. Marie that Newton represented his University in Parliament from 1688 until 1705, during which time he was assiduous in his attendance, but spoke once only, to request the usher to shut a window (t. v. p. 170). In fact he sat three (1689-90, and again 1703-5), not seventeen, years. At p. 162 of the same volume we meet the surprising statement that Halley predicted for 1682 the return of the comet observed by Kepler in 1607. It is almost superfluous to remark that its appearance in 1682 was as unlooked-for as that of any of its predecessors, that its periodical character was then first divined, and in 1759 verified.

The observation made by Wilcke in 1787 that the auroral corona forms in the magnetic zenith is attributed by our author to De Mairan in 1747. The eminent Academician, we can assure him, would have been the last to welcome a remark so subversive of the arguments by which he sought to efface the magnetic character of the phenomenon. Neither is it the case that Halley noticed the bisection of the auroral arch by the magnetic meridian. Obvious though the coincidence appear, it was first pointed out by Ussher in 1788.

We note further M. Marie's curious incredulity as to the authentic measurement, so far, of the parallax of any single star; his statements that the accepted value of the solar parallax is 8″·5 (t. ix. p. 43), that the mass of the moon is $\frac{1}{88}$ that of the earth, and that Herschel detected interstitial movements in resolvable nebulæ (t. ix. p. 145); finally, his ascription to Sir *William* Herschel of the translation of Lacroix' "Differential Calculus" executed by his son conjointly with Babbage and Peacock.

These and other similar blemishes, however, are very far outweighed by the merits of the work in which they occur. It is one of marked individuality; and individuality lends interest, if it sometimes begets defects. No student of the higher mathematics should leave it unread; its perusal cannot fail to afford pleasure, as well as to widen comprehension of modern methods by their comparison with those they have succeeded, and by the intelligent survey of their growth in the past.

CHEMISTRY OF WHEAT, FLOUR, AND BREAD

Chemistry of Wheat, Flour, and Bread, and Technology of Bread-making. By William Jago. (Brighton: Published by the Author, 1886.)

THIS bulky volume professes to treat of its subjects in an exhaustive manner. Wheat, flour, and bread-making are as important as they are universal; and if they are common-place, their study requires deep insight into chemical science. Mr. Jago's book will form a valuable addition to economic science. The composition of wheats from all parts of the world, the minute structure of the grain, the composition of milling products, and the processes of panary fermentation, fall properly within the limits of such a work, and are dealt with in an exceedingly painstaking manner. The various methods of bread-making, the chemistry of the art, and the effects of blending different descriptions of wheat so as to secure the best possible results, are amply and ably discussed. Modern milling and baking appliances are also described carefully and illustrated graphically. There is likewise enough of the author's own thought and research to redeem the work from the stigma of being mere compilation. The book is decidedly useful, and, making due allowance for the progressive state of our knowledge upon many of the topics dealt with, it will probably be received as a standard work. It brings within its ample limits a vast

amount of information which has usually, and we think appropriately, been treated of by separate authorities. The book is, in fact, a sort of encyclopædia of bread-making, and this being the case, it is open to the faults of such works. The design or scope is too large, and the matter introduced to our notice is often too remotely relevant to the immediate wants of the reader. A definition of chemistry, a table of atomic weights, an explanation of chemical equations, atoms and molecules, are scarcely necessary in this connection. Similarly, we cannot approve of lessons upon polarisation of light, the uses of the microscope, and the *camera lucida* being introduced *in extenso* into a book specially treating of a technical subject like this. Such knowledge ought to be assumed as already possessed by the reader; and as well might the author have given instruction upon the origin and uses of decimal fractions, or led up to his subject by several preliminary volumes dealing with the whole "circle of the sciences." Certainly he lays himself open to the charge of instructing either too much or too little. He deals with abstract scientific problems lying at the root of chemistry, and with the vulgar processes of the cook and the baker; and treats with equal facility of the microscope and the flour-mill. We had rather leave the minuter criticism of this voluminous work to the many experts whom it concerns, and who will no doubt be ready to detect any errors into which the indefatigable and talented author may have fallen. If Mr. Jago is ever tempted to bring out a second edition, we may recommend the use of the pruning-knife, which, if judiciously and freely used, will leave a better proportioned but less bulky treatise in our hands.

JOHN WRIGHTSON

OUR BOOK SHELF

American Journal of Mathematics, vol. viii. No. 3. (Baltimore, July 1886.)

IN her note on "the binomial equation $x^p - 1 = 0$," Miss Scott gives a somewhat simpler form of the equation for quartisection than that given by Prof. Cayley (*L.Math. S.Proc.*, vol. xi. pp. 11-14), and works out the equation for quinquisection on apparently different lines from Mr. F. S. Carey's solution (cf. Prof. Cayley, *L.Math.S.Proc.*, vol. xii. and vol. xvi.). Mr. F. N. Cole furnishes "A Contribution to the Theory of the General Equation of the Sixth Degree," which is interesting from the historical details which he gives. He acknowledges his great indebtedness to Klein, but there is a good deal of original work in the note. Mr. J. C. Fields gives a neat "proof of the elliptic-function addition-theorem." The *pièce de résistance* of the number is, however, the long-looked-for notes of "Lectures on the Theory of Reciprocants," by Prof. Sylvester. These are designed as "a practical introduction to an enlarged theory of algebraical forms, and, as such, are not constructed with the rigorous adhesion to logical order which might be properly expected in a systematic treatise. The object of the lecturer was to rouse an interest in the subject, and in pursuit of this end he has not hesitated to state many results, by way of anticipation, which might, with stricter regard to method, have followed at a later point in the course." The lectures, which are ten in number, have been reported by Mr. J. Hammond. The subject, which, it will be remembered, was fully brought before our readers by Prof. Sylvester's inaugural lecture, printed *in extenso* in NATURE (vol. xxxiii. pp. 222-231), has already attracted many of our younger mathematicians, so that there is hope of the Professor's closing aspiration of creating "such a school of mathematics as might go some way at least to revive the old scientific renown of Oxford" being soon an accomplished fact.

The Non-Euclidian Geometry Vindicated: a Reply to Mr. Skey. (*Transactions* of Wellington Philosophical Society.)

A PAPER entitled "On the Simplest Continuous Manifoldness of Two Dimensions and of Finite Extent," by Mr. F. W. Frankland, was read before the London Mathematical Society, December 14, 1876 (*Proc.*, vol. viii. pp. 57-64), and was subsequently published in our columns (vol. xv. p. 515) This same paper, or one of similar character with identical title, appears to have given rise to a paper by Mr. Skey, which took the form of notes on Mr. Frankland's paper, and was read before the Wellington Philosophical Society on June 26, 1880 (published in the thirteenth volume of the *Transactions* of the New Zealand Institute). The pamphlet before us is an abridgment of a series of letters in which Mr. Frankland convincingly replies *seriatim* to the main points raised by Mr. Skey, and maintains his former ground by additional arguments.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

The Sense of Smell

I KNOW a person who has never been conscious of any odour from a bed of mignonette, and I know another person who has never been conscious of any odour from a bean-field. Both of these persons have the sense of smell acute and discriminating as regards other odours.

I know persons who cannot discover a difference between certain odours which are very different to ordinary persons. Then there are persons who are sickened by certain odours which usually give pleasure. A considerable number of persons seem to be altogether destitute of the sense of smell; and on the other hand there are a few who have the sense very strongly developed.

I am at present investigating peculiarities of this sense, and I shall feel obliged to any one who will furnish me with illustrations or examples—whatever their character may be—with such fullness and precision as will enable me to use them in a scientific inquiry.

ARTHUR MITCHELL

34, Drummond Place, Edinburgh, September 24

Palæolithic Implements in Cambridgeshire

FEW Palæolithic implements have, I believe, been discovered in Cambridgeshire, although they are abundant in the gravels of the neighbouring counties of Suffolk and Essex. It may therefore interest your readers to learn that three implements have lately been found near Kennet, on the surface of a field not far from the high-road from Newmarket to Thetford. Two of the implements are kite-shaped. One, of lustrous black flint, is acutely pointed, with sharp cutting edges, and has a part of the original crust of the flint left on one of the faces, which is less convex than the other. It has lost a portion of the butt-end, but is otherwise perfect. The third is a sharp-rimmed ovate implement, the surface of which is stained a deep ochreous colour. Portions of the original crust remain on the faces and base.

Two other implements of the pointed type have been found on the surface near Kennet, but are not in my possession.

In the winter of 1884-85 several implements and flakes were

found in a ballast-pit opened by the Great Eastern Railway Company by the side of the line, about a mile and a quarter from Kennet Station, in the county of Suffolk. A reference to the Geological Map of the Ordnance Survey, Sheet 51, N.E., will show that the gravel in which this pit was opened is an extension of that which underlies the site of the above *surface* discovery. The implements from the ballast-pit which have come into my possession are of the kite-shaped and ovate types. Some are water-worn and abraded, in others the angles and edges are as sharp as if made yesterday.

ARTHUR G. WRIGHT

Sign-Numbers in Use among the Masai

AMONG the numerous tribes of Central Africa the Masai are distinguished by their use of finger-signs to denote numbers. These notorious warriors rarely ever use language to indicate numbers without accompanying signs on the fingers, though very frequently the latter are employed without the former, especially in answering questions.

As by some inadvertency I omitted giving a list of these signs in "Through Masai-Land," and Mr. Johnston, in his book "Kilimanjaro," has followed suit, it may still be of some interest and value to anthropologists to learn what these are.

English	Masai	Sign
1	Nabo	First finger held out alone
2	Aré	First and second fingers held out and alternately moved backwards and forwards
3	Uni	Thumb and two first fingers placed tip to tip
4	Unghwani	First and second fingers laid on top of each other
5	Umiēt	Thumb placed between first and second fingers
6	Ilé	Thumb scratched over nail of second finger
7	Nabishana	No finger indication
8	Usiēt	Hand held open and vertical and moved up and down
9	Naūdo	Thumb and first finger form a circle by joining the tips
10	Tomon	First finger drawn over the nail of the thumb
11	Tomoni-obwo	Same sign as in 10 accompanied by that for 1. The same rule for the succeeding numbers
20	Tikitum	The hand closed and opened rapidly
21	Tikitum-o-nabo	The same as 20, but followed by the sign for 1
30	Othman	First finger held out and shaken by a circular movement of the wrist
40	Artum	The hand held open and vertical and shaken or agitated by a circular movement of the wrist; not up and down as in 8
50	Unum	Thumb placed between first and second fingers, and hand agitated as in 40
60	Tomoni-ilé	Nail of thumb scratched on nail of third finger
70	Tomoni-nabishana	No finger indication
80	Tomoni-usiēt	Same as in 8, but sign never employed alone
90	Tomoni-naūdo	Same as in 9, but words always employed along with sign
100	Ipé	The partially closed hand opened once or twice
200	Ipé-aré	

JOSEPH THOMSON

A GLACIAL PERIOD IN AUSTRALIA

A GREAT many theories have been put forward to explain the extensive glaciation which repeatedly covered Europe and North America with enormous ice-streams. The ingenuity displayed by those who dealt with the subject was well worthy of the importance which attaches to the solution of the problem. However plausible some of the theories propounded may be, still it seems premature to approach such a question until all the available evidence bearing on the subject has been brought together. The southern hemisphere has, up till very recently, revealed only a few, and not very important facts, regarding glaciation, and it is evident that glacier traces in that hemisphere must be of great importance to explain the cause of glaciation; whether we may suppose it to be cosmic or terrestrial. I think, therefore, that my discoveries of glacier traces in Australia may be of sufficient general scientific interest to warrant my giving a short account of them in this journal.

Dr. von Haast, in his excellent work on the "Geology of Canterbury and Westland (New Zealand)" gave a detailed account of the traces of an extensive glaciation in the Middle Island of New Zealand, together with a map, showing that at one time the glaciers on the western slopes of the Southern Alps in many places reached down to the sea, and that those which descended from their eastern flanks covered a large portion of the lowlands extending between the mountains and the coast-line.

During my exploration of the central part of the Southern Alps I observed numerous old moraines and *roches moutonnées* in the area which, according to von Haast's map, had once been covered by glaciers. Particularly was I struck with the freshness of the striæ, the scratches and grooves in the steep and rocky precipices on the sides of Milford Sound, that jewel of the Southern Alps.[1] Capt. Hutton, who examined some of the other sounds has not discovered any glacial traces there.[2]

Even now the glaciers in New Zealand reach down to 700 feet on the west, and to 2000 feet on the east side, which shows that New Zealand must be subject to a very different climate to that in similar latitudes—44°—in the northern hemisphere. Like Patagonia, New Zealand is at the present day to a certain extent *in a Glacial period*. The much greater extent of the prehistoric glaciers shows, however, that it is now by no means *at the height* of its glaciation.

Although a Glacial period was shown to have existed in New Zealand, there have not up to now been any definite statements regarding this subject in the mainland of Australia. The Rev. Tenison-Woods[3] examined certain rocks in the Blue Mountains, an insignificant table-land to the west of Sydney, and came to the conclusion that these, which had been supposed to indicate ice-action, did not do so, and that in fact there was no evidence of a Glacial period in the Blue Mountains. Mr. Howitt[4] came to a similar negative result regarding certain gravels and conglomerates, which according to others indicated glacial action. Griffiths,[5] on the other hand, claims these and other conglomerates of Omeo and Gippsland as evidences of a Glacial period in Australia.

Prof. Tate[6] described some striated rocks found near Adelaide, and Stirling[7] has shown that there exist extensive traces of glacier action in certain valleys near Omeo.

I myself have,[8] in several papers, published some of

the results of my two explorations of the Australian Alps, and described numerous indubitable traces of prehistoric glaciers on Mount Kosciusco and on Mount Bogong.[1]

Mr. Brown, Government Geologist of South Australia, has furnished me with photographs of beautifully preserved striæ on rocks in the Mount Lofty group near Adelaide. Prof. Hutton [2] has taken objection to the conclusions arrived at by myself, and although he acknowledges a *Glacier* period in Australia, objects to its having been a *Glacial* period. If I now revise the facts stated by others, and compare them with my own observations, I hope I may be able to give some idea as to the time and extent of the Glacial period in Australia. Before entering on the subject, however, I must give an outline of the physiography of the Australian Alps.

The greater part of Australia is destitute of high mountains; only in the south-eastern corner we meet with greater elevations. Here a true Alpine chain is situated. These Australian Alps consist of numerous parallel chains extending from south to north, which are curved in such a way as to advance with their convex sides eastward. The Australian Alps are very old; only Palæozoic formations participate in the folding which runs parallel to the extent of the ridges. The predominant rocks on the surface are gneiss-granite and Silurian, which appears generally in the facies of brown slate. Devonian limestones and slates are found; they are, however, not common and discordant to the underlying Silurian. The stratified rocks are highly folded, and usually with a very large dip or vertical. The Silurian appears on the surface in elongated islands or bands (compare the Government geological map of New South Wales), which extend parallel to the strike and to the main ranges. The coast-line follows precisely the same direction as the mountain-ranges, and the contour lines on the steep submarine precipice which extends down from it also run in the same direction. It appears that these mountains have been formed by a process of folding consequent on a horizontal pressure acting from west to east, and moving the folds in that direction away from a centre of depression *situated in the interior of Australia*. The steep submarine precipice by which the land sinks abruptly to a very great depth appears *as a more recent fault*.

Volcanic action participated in the formation of the Australian Alps, particularly in the vicinity of Mount Bogong. The volcanoes which formed the Bogong basalt plains, &c., seem to have been active during the early part of the Devonian. It appears probable that the upheaval of the Australian Alps—the folding—took place between the Silurian and Devonian or in the ealy Devonian. Hardly any formations later than the Palæozoic take part in the formation of the Australian Alps, and those which, like the Miocene in the valleys, have been observed, show a perfectly undisturbed horizontal stratification.

It will be seen from this that the Australian Alps are *very old*, much older not only than the European Alps and Himalayas, but older also than the New Zealand Alps. The effects of erosion are consequently much more matured there than in the other mountain systems mentioned, and consequently the appearance of these mountains is of particular interest. Only here and there rocks crop out on the summits of the hills or form steep precipices on their sides. Generally speaking, the mountain forms are very tame, and round. Mountaineering in Australia can generally be performed on horseback. The basements of high massive elevations only are left. High and sharp ridges weathered into series of grotesque rock pinnacles, the characteristic of the much younger Alps of Europe, have long since disappeared, and extensive undulating table-lands now mark the localities where once high peaks have stood. These table-lands are well defined and surrounded by steeper inclines, by which they descend to the surrounding lowlands. The Kosciusco group, from which the highest mountains in Australia arise, is a remarkable example of such a table-land, extending over an area of 160 square miles, with an average height of 5600–6000 feet.

The highest mountain in Australia, Mount Townsend, which I discovered to be the culminating point of Australia, is 7351 feet high.[1] There are several other peaks in the Kosciusco group over 7000 feet, particularly Mueller's Peak, 7266 feet, which was, up to the time of my expedition, considered the highest. Two peaks, which I have named Abbott's Peak and Mount Clarke, are over 7100 feet high.

In other parts of the Australian Alps the height of 7000 feet is nowhere reached. Next in importance to the Kosciusco group is the Bogong range, the highest point of which was ascended by me this year; it is 6508 feet above sea-level. Other peaks on the basaltic plateau south of Mount Bogong attain a height of 6000–6400 feet.

The whole of the Australian Alps consists of several high table-lands divided by very broken and hilly country from each other. The lowest levels on the table-lands are usually higher than the hill-tops in the adjacent country. The valleys are cut deep into the land. The main Alpine valleys have in their upper and middle portions an elevation of about 2000 feet. Steep gorges and waterfalls occur only on the margins of the table-lands. Terraces in the valleys themselves are not met with.

The Australian Alps reach to the sea. The whole of the south-eastern coast of Australia is hilly. Towards the west and north-west they dive under the Tertiary plains through which the Murray River wends its way. In the north they terminate on the left bank of the Yass and right bank of the Shoalhaven River. The mountainous country extends beyond this line to the north-eastern corner of Australia with a similar direction of the chains; but in this locality the geological structure changes. Extensive Triassic and Carboniferous formations take the place of the gneiss-granite and Silurian of the Australian Alps South-west the Alps may be considered to terminate near Melbourne.

The Australian Alps, from the Murray plain to the sea, have a width of about 120 miles on an average, and they are, from Melbourne to the Yass River, nearly 400 miles long. They are situated between 35° and 39° S. lat. and 145° and 150° E. long. Their latitude accordingly corresponds to that of the Sierra Nevada.

The Australian Alps exercise a vast influence on the climate and rainfall, in such a manner that, whilst the greater part of Australia south of the zone of tropical rains, suffers exceedingly from want of rain, the south-east corner—the Alpine part of Australia—has sufficient rainfall for the development of the country. To this climatic influence of the Australian Alps the great superiority of the colonies of New South Wales and Victoria over all the other Australian colonies must be ascribed.

At Kiandra, situated to the north of the Kosciusco group, the only meteorological station at a high elevation, there is a very heavy rainfall; from there it rapidly decreases as we advance westwards towards the interior, and also to the east, although not so much. It increases again on the east coast.

The Eucalyptus forests of the lowlands extend up to a height of about 5800 feet. Higher elevations are destitute of trees. On the upper margin of tree-growth the forest consists of very low and stunted trees belonging to the species *Eucalyptus pauciflora* and *E. Gunnii*. This Alpine forest resembles "Krummholz" of our Alps.

[1] A detailed account of the results of my explorations will be published in the Ergänzungshefte zu *Petermann's Geografischen Mittheilungen*.

[2] Hutton, "The Supposed Glacial Period in Australia," *Proceedings* of the Linnean Society of New South Wales for 1885.

[1] I made the ascent of Mueller's Peak, the height of which was trigonometrically measured by the Victorian Geodetical Survey (Mr. Black), and Mount Townsend on the same day, and the height given above was calculated from the aneroid readings on *both peaks*.

It snows in the Australian Alps very much in the winter, and the prevailing westerly winter winds pile up masses of wind-blown snow just below the high ridges on their eastern or lee side. These masses of snow never disappear altogether in summer, and we find eternal snow in the Australian Alps at an elevation of 6500 feet.

The excessively clear and bright Australian atmosphere affords no obstacle to the nocturnal irradiation of the day's heat, and so it freezes very frequently there at night, even in midsummer, down to 5000 feet. I experienced severe frosts on Mount Kosciusco in January 1885 —January corresponds to our July—whilst it was intensely hot in the adjacent lowlands.

From these statements it is evident that we have in the Australian Alps a formidable mountain-range, which, although not glaciated now, would bear glaciers if the climate were slightly colder and more humid.

It seemed particularly surprising, therefore, that the older authors on Australian glaciation had given a verdict without examining the Alps. If no glacier traces were found in the lowlands, they yet might be found in the Alps; and if glacier traces were found in the lowlands, how much more extensive must they be in the mountains. Up the mountains I accordingly went to look for them. I undertook two expeditions. In 1885 I visited the Kosciusco group and ascended Mueller's Peak and Mount Townsend, and this year I explored the Bogong range and ascended the highest mountain in Victoria, Mount Bogong.

The Governments and learned Societies of New South Wales and Victoria greatly assisted me in my work by pecuniary aid and in other ways, and I am glad here to find an opportunity of expressing my gratitude for the great—I might say splendid—liberality with which the Australians have aided me. On my second journey I was accompanied by Mr. James Stirling, District Surveyor of Omeo, whose well-known essays on Australian glaciation have closely connected his name with the subject I had in view.

I was favoured with fine weather on both occasions, and on both occasions travelled through country never previously explored by any one with practical mountaineering experience. North of Mount Bogong I travelled for three days through country hitherto unknown. I found glacier traces on both occasions in great abundance, and in a sufficient state of preservation to be recognised as such without the shadow of a doubt. On the sides of the valleys of the tributaries to the Snowy River, which drains the eastern slopes of the Kosciusco plateau, I found abundant *roches moutonnées* at levels over 5800 feet, and high above the bottoms of the valleys. Also in some parts of the table-land itself such were found. With a little Alpine experience it is not difficult to discriminate between such ice-worn rocks and the ordinary bosses of weathered granite. These rocks are particularly well-defined in the Wilkinson Valley, the upper part of which is situated between Mount Townsend and Mueller's Peak. The bottom of the upper part of this valley is a broad and flat plain 6260 feet above sea-level. The hill-sides which surround it are everywhere worn down by glacial action up to about 800 feet above the valley bottom. The upper limit of ice-action is clearly marked, as in many valleys of the European Alps, and the thickness of the prehistoric ice stream thereby clearly indicated.

On the southern slopes of Mount Bogong, and also on the spurs of the northern flank of the mountain, basaltic erratics were found, which rocks could hardly have been transported to that locality without ice-action. In the valley of Mountain Creek, to the north of Mount Bogong, we discovered a large and well-preserved terminal moraine at an elevation of about 2800 feet, and some traces of others further down the valley.

The large moraine was carefully studied by Mr. Stirling and myself. Rocks of various kinds are scattered irregularly in it. It extends from one side of the broad valley to the other, and is cut through near the centre by the Mountain Creek. On the steep slopes towards the stream its composition of rocks brought down by an ice-stream can be easily recognised.

These two expeditions to the Australian Alps convinced me that at one time these mountains were glaciated, and the discovery of the moraine in Mountain Creek Valley, together with Stirling's (*l.c.*) elaborate researches in the Livingstone Valley, prove that the ice-streams of the Glacial period must have descended to pretty low levels. Down to 2000 feet glacial traces have been found in various parts of the Alps, and also in the Lofty Mountains near Adelaide. It is assumed by C. Wilkinson and other leading Australian geologists that a pluviatile period existed in the Miocene period, and it is obvious that such a period would probably be isochronous with the glaciation at high levels.

It is difficult to say whether the Australian and New Zealand glaciation was simultaneous, but that also appears probable. The better preservation of striæ, &c., in New Zealand is doubtless due to the greater hardness and resisting power to meteorological influences, of the ice-worn rocks in New Zealand than in the Australian Alps, where rapidly weathering granite is prevalent.

Whether this glaciation of Australasia was simultaneous with the last glaciation of Europe, or whether it was in time situated between the last glaciation and the last but one of the northern hemisphere, is not easy to decide. It appears nearly certain that it was *not later* than the last European Glacial period, and, as far as my opinion of the appearance of the traces it left behind goes, it was *earlier*. It may be hoped that future researches will show in a decisive manner whether it was simultaneous or earlier. If we do not consider merely local circumstances of sufficient effect to produce such a great change of climate as to cause so extensive a glaciation, we may, by arriving at the decision of the time of the Glacial period in Australia, also ascertain whether Glacial periods in the southern and northern hemispheres are *simultaneous or alternating*, which would give a clue to the difficult problem before us.

The necessary researches will doubtless be carried on with vigour by Australian men of science; and we may hope that their sagacity and perseverance may lead to the solution of the question, What is the cause of Glacial periods?

R. VON LENDENFELD

ROOTS [1]

IT is a fact which has become more and more evident to the practical cultivator that the results of his efforts manifest themselves on the whole in a sort of compromise between the plant and its environment: I mean that although he sees more or less distinctly what his plant should be—according to a certain standard, however—it is but rarely, if ever, that the plant cultivated perfectly fulfils in every respect what is demanded of it. Of late years this has of course forced itself more prominently before the observer, because the facts and phenomena constituting what is termed variation have been so much more definitely described, and the questions arising out of them so much more clearly formulated.

Two points can be asserted without fear of contradiction: first, the plant itself is a variable organism; and, secondly, its environment varies. Now within limits which are somewhat wide, when closely examined, the experience of man leads him to neglect the variations occurring around him, and so no one quarrels with the statement that two individual geraniums belong to the same variety, or two oak trees to the same species,

[1] See NATURE, vol. xxxi. p. 183. A lecture by H. Marshall Ward, M.A., F.L.S, Fellow of Christ's College, Cambridge; Professor of Botany in the School of Forestry, Royal Indian College, Cooper's Hill.

although an accurate description of each of the two geraniums or of the two oaks might require very different wording.

It has also become more and more evident that although we cannot ascribe all variations to their causes —very often, indeed, we cannot even suggest causes for them—there are nevertheless numerous deviations from the normal, so to speak, exhibited by plants which can be distinctly referred to certain deviations from the normal on the part of their environment.

To illustrate this we may take the case of two plants of that very common weed, the Shepherd's Purse, growing at different ends of the same small plot of ground: the soil is sandy, and so much alike all over as to be regarded as the same everywhere, nevertheless the plant at one end is large, more than a foot high, and luxuriant, with many leaves and flowers, and eventually produces numerous seeds, whereas that at the other end is small, less than 4 inches high, and bears but a few stunted leaves and three or four poor flowers and fruits. The cause of the difference is found to be the different supply of water in the two cases, and if any one doubts that this may be so, let him try the experiment of growing two or more specimens of this weed in pots: the pots to be new, filled with soil which has been thoroughly mixed, and all the pots exposed to the same conditions—*i.e.* practically the same—except that those of one series are watered sufficiently often, and those of the other only just sufficient to keep the plant actually living. The experiment is easy and conclusive with such a weed as the above. Now, it is just such experiments as that above described—some of them equally simple, others less so—that the physiologist devotes much of his attention to, and in just such a manner has been gathered together a nucleus of information around which more knowledge can be grouped.

I may make these points clearer by again quoting an illustration, and, not to confuse or mislead you by going too far afield, I will keep to the same line of investigation, partly because it is quite as simple and conclusive as any other of many that might be selected, and partly because it may be possible to set before you some facts which are interesting or even new to you.

It has been found that in some cases where two plants are growing in the same soil and under the same conditions as above, but where one plant receives less water than the other, that the dwarfed drier plant is more hairy than the larger and luxuriantly growing plant, which has been well watered. On looking more closely into this matter it turns out that the extra hairiness is (in some cases at any rate) simply due to the fact that the hairs are closer together, because the little cells on the outer parts of the plant which grow out into hairs do not increase so much in length and superficial extent as those on the well-watered plant, and thus the hairs stand thicker together on the same superficial area of the organ —of a leaf, for instance. In other cases, however, the hairs are really increased in numbers and length—the plant is absolutely more hairy. It will be noticed that details concerning growth and turgidity, and of the influence of various minerals, and so on, are not under consideration here. I am not asserting that all cases of hairiness in plants are to be ascribed to this cause; but it does occur, as stated, and the point is a curious one in view of the fact that very many plants which grow in sandy dry soils are conspicuously hairy, whereas allied species growing in or near water, or even only in moister situations, are devoid of conspicuous hairs, or even quite smooth.

The above peculiarity is not confined to leaves and stems, moreover, for experiments with roots have shown that the root-hairs, which are so important in collecting moisture, &c., from the soil, can be made to appear in enormons numbers when the root is kept in a soil which is very open and only slightly moist, whereas none or very few are developed on the same roots growing in water: this again is in accordance generally with the fact that the roots of land-plants growing in light soils develop innumerable root-hairs, whereas those of water-plants do not thus increase their surface and points of attachment. I cannot here go into all the interesting facts known about these hairs, but it will be sufficient if you bear in mind the main points just mentioned.

Let us now vary the experiments a little. It is obvious that we might suppose any number of differences in the amount of water given to the plants used in the experiments described above; but it would be found, as matter of fact, that however little be the quantity of water given to the soil in which the dwarfed plant is, compared with that put into the soil in which the luxuriant plant grows, the actual weight of water will nevertheless have to be considerable, taking the whole life of the plant into consideration—there will be more used than you probably know, moreover, because the soil itself will no doubt condense and absorb some from the atmosphere during the night. There is a minimum of water absolutely necessary, and if the plant does not obtain this it will die. Its death will be ushered in by drooping and withering of the leaves, stem, and roots, and this condition, in which the functions of the plant are interfered with beyond a certain point, passes into a condition of disease.

Now take another case. We might so arrange the experiment that we poured and continued to pour too much water into the soil. Here again it would be found that a condition of disease eventually sets in—*i.e.* a condition in which the functions of the plant are again interfered with beyond a certain point. The symptoms and progress of the disease will be very different in the latter case, however, from those in the former. It may also be mentioned that in neither experiment is death inevitable if the disturbing cause is removed soon enough—*i.e.* if sufficient water be added in the first case before the cells have ceased to be able to take it up, or if the previous conditions of the soil are restored soon enough in the case of the over-watered plant.

Here we come to a matter which is less simple than may appear at first sight. You will note that the problem in the latter case is to restore the previous conditions of the roots and soil soon enough; I put it thus, because the conditions of the roots and soil may soon be very profoundly altered by the over-watering.

To understand this, it is necessary to become a little more fully acquainted with the condition of affairs in what may be called the normal case, where the soil is light and open, and plenty of water but not too much is at the disposal of the roots. Such a soil will consist of innumerable fine particles, of different shapes, sizes, and composition. No doubt there will be grains of quartz, particles of broken up vegetable matter, and little rugged bits of stones containing various minerals; each of these tiny fragments will be covered with a thin layer of water, and you would probably be greatly surprised if I were to go into the proofs showing how extremely tenacious of its water-blanket each particle is. It may be enough for our present purpose if you accept the fact that it requires enormous force to deprive the particles of the last traces of their water-layers; they will give off some—or in some cases even a good deal—rather easily, and in fact when the layers become of a certain thickness no more water can attach itself to the particles, but it falls away and the soil remains saturated, as we say.

Now these particles of soil, each enveloped in its water-blanket, are not in close contact; there are spaces between them, and these interspaces influence the quantity of water which can be held back by the soil.

Let us suppose such a soil perfectly dry; the particles above referred to being irregular in shape and size, and only roughly in contact at various points, the interspaces will be filled with air. If water be then added in some

quantity, each of the particles becomes clothed with a layer of water, and some of the air is driven out, though bubbles of air will still exist in the larger interspaces.

A third case is conceivable—so much water might be supposed to find its way in, that no air remained in the interspaces between the particles of soil. Now it is true that such a state of affairs is not readily brought about in a normal soil; but I may indicate how the result is occasionally attained to a great extent. Suppose that a layer of clay or other impenetrable subsoil lies beneath the soil in question; then if water oozes into the soil in larger quantities than can be got rid of in the time, it is possible for nearly all the air to be displaced. Of course the object of good drainage is to prevent this; and it is often overlooked that drainage from below has the effect of drawing in air as well as of running off superfluous water—air is driven into the spaces as the water leaves them.

In speaking of the "bubbles of air" entangled in the interspaces between the particles of soil, each with its water-blanket, I have overlooked some details as to what the bubbles really are. As a matter of fact they will not remain of the same composition as ordinary air, and may soon differ considerably; besides the vapour of water, they may contain gases in quite different proportions from those in the air outside. In the type case, however, there will be some oxygen present in the bubbles.

It is not intended here to go very fully into a description of the structure of the roots of land-plants; enough if you are reminded how the smaller ramifications of a root are found to be more numerous and thinner as we approach the periphery of the mass of earth which they traverse. From the youngest rootlets are produced the root-hairs, in enormous quantities, new ones arising forwards—*i.e.* near the tip of the rootlet—as the rootlet grows on, and those behind dying off after fulfilling their functions. These functions are chiefly to apply themselves in the closest manner to the surfaces of the particles of soil, and in this way to place the water which they contain in direct continuity with the water which clings with such enormous force to the surfaces of the particles. Hence this water can pass from the soil to the plant, and anything dissolved in the water can also pass into the root-hair and thus up into the plant.

I am not going to dwell on how the root hairs themselves aid in dissolving mineral substances—corroding the surfaces of the particles of soil they cling to—nor shall I trouble you with the details of what substances will be dissolved in the water; for, of course, you will see that anything soluble will pass into solution and may be carried into the plant.

The chief point to be insisted on just now is that this water in the soil will contain among other substances oxygen dissolved in it from the air-bubbles referred to above, and that this dissolved oxygen will pass into the root-hairs in solution together with the minerals and any other substances. This oxygen, moreover, is absolutely indispensable for the life of the root-hairs; it can be easily shown that if the supply of oxygen is stopped, or even diminished to any considerable extent, the roots begin to die, because the root-hairs cease to act.

Let us look a little more closely into this point. Each root-hair is a tiny cell containing living protoplasm and certain other substances, all inclosed in a thin, elastic, porous membrane. Now it has been abundantly proved that if such a cell is deprived of oxygen, its protoplasm becomes dormant for a time, and slowly breaks up, as it were; subsequently it becomes decomposed into other and simpler materials. A sort of internal combustion and fermentation take place, and these processes result in the formation and liberation of bodies like carbon-dioxide, alcohol, acetic acid, and other acid matters—substances in the main not only incapable of supporting the life of the root-hairs but actually destructive of it.

Evidently, then, if we deprive all the root-hairs of oxygen, they will eventually die. Their death will entail that of the rootlets and roots to which they belong, and this for two obvious reasons—first, it is the root-hairs and the root-hairs alone which can absorb the necessary water and substances in solution from the soil to supply such a plant as we are concerned with; and, secondly, the noxious products resulting from their death accumulate in the soil and diffuse into the root, and so hasten similar decompositions in what were hitherto healthy cells.

It must not be supposed that these disastrous consequences of the deprivation of oxygen always follow immediately. Not only are the roots of some trees, for instance, able to withstand ill-treatment longer than others, but, obviously, the kind and degree of ill-treatment may affect the problem of how long the plant shall survive. The number of rootlets and root-hairs, and the spread of the roots and other factors, will obviously affect the matter.

Suppose the following case as an example. A young tree is growing and flourishing in an open, good soil, and, for some reason or other, more soil is heaped about the roots until the depth is increased considerably: the deeper situation has placed obstacles in the way of the roots obtaining oxygen so readily as before. Not only are the roots further from the atmosphere, but the water carried down has to percolate through more soil, and may part with much of its oxygen (or even all) on the way: of course the nature of the soil, the presence of organic matters, and other circumstances decide this. It is not at all difficult to conceive of such a case where the supply of oxygen to the roots is thus diminished so far that the activity of the root-hairs as a whole is simply lowered, but not destroyed,—a stage or two further and they might become dormant, and their protoplasm undergo intramolecular respiration for a time, and break up. It is clear that the diminished activity of the roots will affect the supply of water (and the substances dissolved in it) to the leaves: this will obviously react on the thickness of the annual rings, and this again on future supplies—since the water passes up the alburnum or young outer layers of woody tissue. Moreover, a diminution of supplies from the leaves means less substance and power for replacing the root-hairs, and so on. In this way it may require some time to kill the tree, and all kinds of complications may arise meanwhile. This case is probably by no means uncommon.

A more extreme case is where the soil becomes damp and clogged with excessive moisture: not only does no oxygen reach the roots, but noxious gases accumulate in solution in the soil, and will hurry matters by poisoning cells which might otherwise live a longer life of usefulness. It is extremely probable that such gases find their way into higher parts of the plant in the air-bubbles known to exist and to undergo alterations of pressure in the vessels of the wood: this being so, they would slowly retard the action of other living cells, and so affect the upper parts of the plant even more rapidly than would otherwise be the case. Damp soil may thus do injury according to its depth and nature; but it need not necessarily be deep to be injurious if much oxygen-consuming substance is present. I have seen excellent soil converted into damp, stinking, deadly stuff from the action and accumulation of the larvæ of cockchafers: these "grubs" may, it is true, accelerate the devastation caused by the consumption of oxygen and the accumulation of poisonous waste matters in the soil by directly cutting off portions of the roots themselves, but the accumulation of oxygen-consuming substance, and the cutting off of supplies to the root-hairs evidently plays a chief part in the destruction.

There is another matter with regard to damp soils that cannot be left out of account. I have already told you that roots which are developed in water or in very damp sandy soil—and which are perfectly healthy—have

few or no root hairs formed on their surfaces; whereas it may be readily shown that the roots of the same plant growing in a well-aërated open soil, which is scarcely moist to all appearance, will be densely covered with a close-set pile of hairs. Indeed it is by means of the millions of root-hairs on its rootlets that a sunflower or a bean, for instance, obtains the enormous quantities of water necessary for its needs from soil which, to our rough perception, seems to be dry.

I cannot here go into all the proofs that such a soil is by no means so dry as it looks; but will simply remind you of what was said above as to the enormous force with which the minute particles of rock, &c., which form "soil" retain their hold on the thin films of water which constitute what have been termed their water-blankets. This is certain, that a healthy well-rooted plant can take up water from a soil which is to all appearance air-dry; whereas a plant which has not yet had time to develop its root-hairs in sufficient numbers to take these firmly adherent water-films, from numerous particles of soil, would droop and wither.

Of course it must be borne in mind that we are speaking of land-plants such as we commonly meet with on ordinary dry land: in the case of plants which flourish in bogs or in water there are corresponding differences in the structures of their roots agreeing with the differences of environment. Even such plants need air at their roots, and an excellent illustration of this is is afforded by some willows. Our common osier and other willows grow, as you are aware, in low-lying damp and even boggy places, often flooded: now, it has been found that, if young willows are planted too deep in the soil, they very soon send out new roots—adventitious roots they are often called—close to the surface of the soil, and these roots soon do all the work. There is no doubt that this power enables these willows to live in places that would be fatal to them otherwise; and the same is true of some other plants.

Enough has now been said to show you how necessary it is that some care should be exercised in watering plants, or in exposing them to conditions different from those to which they are accustomed; and, it need scarcely be added, apparently mysterious diseases may sometimes be explained when it is shown that such precautions have been neglected. Any one can quote instances of plants which will grow in some soils and not in others, but no very satisfactory reason is afforded by simply saying that the one soil is suitable and the other not: however, all I have attempted to show you is that some soils are not suitable for some plants because the plants in question need more air at the roots than these particular soils can afford them under the circumstances.

Many plants flourish in an open soil with plenty of sand in it, but will not grow in a stiff wet soil. This is not necessarily because the heavier soil does not contain the right food-materials, but because its particles are so small, so closely packed, and so retentive of moisture, that the root-hairs do not obtain sufficient oxygen: moreover, the very damp state of the soil does not favour the development of the numerous root-hairs necessary, as we have seen. Nor is this all,—though I cannot here enter at length into this point,—root-hairs and roots cannot grow or act unless the temperature is favourable, and we have plenty of evidence to show that a close wet soil may be too cold for the roots at a time when an open drier soil (exposed to similar conditions as regards sunshine, &c.) would be of a temperature favourable to their growth. Many a pot-plant receives an extra over-dose of water because it is drooping from the roots being too cold to act properly. The opening up of stiffer soils by means of the spade or plough, or by the addition of other kinds of soil, such as sand, burnt lime, &c., or by means of drainage of various kinds, is thus to be regarded as a means of letting in air and therefore oxygen to the roots. "Sweetening the soil" is an expression one hears used by planters and others: this is often no doubt their way of expressing the fact that the air thus let in does so much to turn the noxious substances which have accumulated into other substances which the root-hairs of the plant can take up with profit. The exposure of certain soils to sharp winter frosts in part benefits the plants subsequently grown in it, because air can make its way into the cracks produced as the particles crumble: there are other advantages also due to the "weathering" of soils, of course, as also to the addition of lime, &c., but I am purposely abstaining from referring to points concerning the nutrition of plants as generally understood.

Let me shortly call your attention to a few other practical applications of the knowledge briefly summed up above. It is well known that a good deal of experience has been brought to bear on the question of what trees are the best to plant in or near large towns: there are very many facts to be considered. It is not sufficient to find a tree which will accommodate itself to the possibilities of the annual rainfall, or a diminished supply of sunlight throughout the year, and so on; nor is the problem solved when a tree is found that will put up with traces of acid gases in the atmosphere, and, as may follow, the accumulation of acids in the soil, and consequent alterations in its chemical composition. In many cases trees have been found to die as they grew older because the pavement or asphalt over their spreading root-system prevented proper aëration and a proper supply of aërated water to their root-hairs: imagine the effect of a few days' hot summer sunshine on roots just beneath the pavement of an exposed street! It is true the cover may prevent rapid evaporation, but it also shelters the soil from the well-aërated rain-drops; moreover, such sheltered roots will at certain seasons grow up to the surface of the soil and in contact with the lower surface of the pavement. Then there is the question of drainage. If the water which does find its way in slowly accumulates and becomes stagnant, the results are as disastrous or even more so; yet it is obviously a difficult matter so to arrange things that the accumulated surplus water of certain seasons shall pass away below, acting like a suction-pump and drawing in air after it, and still fulfil the other requirements hinted at above. I leave out the question of exhaustion of the soil—the dead leaves, &c., being carefully removed. Can we wonder that there are so few trees to choose from that will stand such treatment? The fact that there are some only accords with what has been already stated—that plants vary in their requirements and powers; and no one doubts that the variations have been influenced by variations in the environment.

We have now seen to a certain extent how variations of a particular kind may affect a plant. The plant responds to a certain extent—it is, as some people say, "plastic"—but if the limits are reached and slightly overstepped, the variations on the part of the plant become dangerous to its existence, and the plant becomes diseased and may die.

Not to dwell upon hypothetical matters, I will content myself with saying, in conclusion, suppose a variety of a given plant grows in damp places and has roots which form few or no root-hairs, and suppose an individual of that plant to become transferred to a more open soil: I have shown you reasons for regarding it as probable that the latter individual might produce more root-hairs and thus adapt itself to the altered conditions. If such a case happened, it is by no means improbable, but the contrary, that other circumstances co-operating or adverse would decide certain problems of importance to the existence of that particular individual.

But the main object of this lecture has been to show you how very complex the conditions may be which bring about a "diseased" condition of the roots. It is no

uncommon event to see a tree flourish for years and then slowly die off from "something at the roots": examination shows that the soil still contains the necessary foods, the water-supply is constant and good, the tree is exposed to no obvious adverse influences, and yet with steps so slow that they are scarcely noticeable, the tree begins to die off before its time. In some cases this is probably because the root-hairs are not receiving their proper supply of atmospheric oxygen, and this may be due to very slight changes in the *structure* (not the chemical composition) of the soil: a very slight diminution in the activity of the root-hairs may cause a diminution in the supply of water to the leaves at seasons when they require much, and this means lessening their supply of food-materials. If the leaves are placed on short commons, they cannot form wood, and so the next season's supply of nutritive solutions may be cut short; moreover, fewer root-hairs will be formed. No doubt differences will appear in different years or seasons; but if the tendency on the whole is in the above direction, the life of the tree is already limited—it may drag on for years as an object, which can scarcely be termed a tree however, but its doom is sealed.

The difficulty of placing one's hand on an exactly illustrative case is due to the fact that other causes are usually at work after a short time. I have purposely avoided any reference to the changes brought about in the chemical nature of a soil by the addition or cutting off of air, &c.; and for the same reason—to keep your attention directed to the root-hairs as living cells exposed to the influence of a definite environment—I have left out of account some questions of food-supply. These matters do not invalidate anything said above, but they do profoundly affect the problems of the diseases of plants, and especially those diseases which start from the roots.

ON THE PROPOSAL TO ESTABLISH A PERMANENT COLONIAL MUSEUM IN LONDON

THE proposal to continue the present Colonial and Indian Exhibition at South Kensington having met with a good deal of support, it is worth while to examine it on its merits; quite apart from the popular accessories of music, illuminations, &c., the continued existence of which depends upon altogether different considerations.

The first point for examination is whether such a permanent exhibition or museum would materially and usefully supplement or form a real addition to the existing public institutions of London, for upon the determination of this question the decision ought largely to depend.

On a general review of the vast collection of objects exhibited in the present Exhibition, they are seen to be mainly included under the four following categories:—

(1) Natural history objects, or specimens of the animal, vegetable, and mineral kingdoms of Nature.

(2) The raw products derived from them, and their economic applications.

(3) Art of every description, with which may be included objects bearing upon archæology and ethnology.

(4) Manufactures of all kinds.

(1) With reference to natural history, it can scarcely be a public desideratum to attempt to form a new museum of this kind when there exists, within a few hundred yards of the Exhibition, the finest collection in the world in the great national Museum of Natural History. There the animals, plants, fossils, and minerals not only of the British colonies, but of the whole known world, are exhibited with a fullness and in a manner that there could not be a possibility of in any way approaching.

(2) Then, as regards the economic uses of the vegetable kingdom at least—such as food-products, drugs, timbers, &c.—the nation possesses in the Museum of Kew Gardens a probably unrivalled public collection admirably exhibited. Many years of energy and a very large expenditure of time and money would fail to make up again such a collection as this has now become.

(3) Objects of art both ancient and modern form a very striking and important portion of the Exhibition. It is probable, however, that the best part of those which are not on loan have been sold or otherwise disposed of, and thus are not available for future exhibition. But with the South Kensington Museum at our doors, the initiation of a new art collection cannot be needed; whilst as for objects illustrative of ethnology and archæological specimens, they are, it is needless to say, magnificently displayed in the galleries of the old British Museum in Bloomsbury.

(4) There remains only the commercial products and manufactures of the colonies and India, and, so far as I am aware, there exists at present no general public collection of such articles. Here then, it appears to me, we have a reasonable basis for the formation of a permanent museum. A public collection of trade samples is a real want in London.

It appears, then, from the above observations, that no necessity exists for a new *general* museum of colonial and Indian productions, inasmuch as the public is already amply provided with other museums which illustrate fully nearly all the objects and articles proposed to be exhibited in the new one.

There is also good reason to think that the multiplication of museums is undesirable as well as unnecessary. We are not without experience of this, and the history of the late India Museum is quite to the point. The vast collections brought together by the Honourable East India Company were quite similar in kind to those it is now proposed to form, and illustrated very thoroughly the productions of India. But the Museum never attracted public interest or proved of much practical utility; many departments were neglected, the specimens badly conserved, and not available for consultation or study, and at last its condition having become somewhat of an official scandal, it was, six or seven years ago, broken up and dispersed. It bears strongly on the remarks above made that the collections had to be distributed among the very museums which I have there enumerated. No doubt additions of much value thus accrued to them; but there was also an immense mass of duplicate and damaged material, some of which at least was destroyed. After this experience it seems scarcely credible that a proposal to form again another general *Indian* Museum in London will be seriously entertained, whatever may be the case as regards the colonies. But in the latter, as in the former, it is almost certain that from similar causes a few years would witness the same history and a similar termination.

It is then, I believe, in a permanent museum of trade samples and of the commercial products of our colonies that a really useful outcome of the present Exhibition is to be sought. The precise scope and character of such a museum would of course require careful consideration; but there is a great and increasing want of some central emporium of a public character where authentic samples, accurately determined and labelled, can be readily inspected and examined by those interested in commercial pursuits. The collection might well be arranged geographically, and should be accompanied by maps, trade statistics, and other aids to inquiry. Under able management such a museum would be capable of rendering great service to the commerce of the Empire, and be the means of bringing into trade the numerous neglected products of the world. I may add, parenthetically, that it would also relieve the staffs of our chief scientific establishments of a good deal of work, involving often much sacrifice of time, which now falls upon them, though outside the scope of their duties.

The situation of such a museum should, however, be

readily accessible to business men, and would be preferably in or close to the City rather than in the West End of London.

HENRY TRIMEN

NOTES

THE International Geodetic Conference will assemble in Berlin on October 20. Its principal business will be to deliberate on the best method of executing the resolutions arrived at at Rome and Washington in 1883 and 1884 respecting the actual measurement of a degree on the earth's surface, and likewise in reference to a scientific survey of the European continent. The adoption by all nations of Greenwich as the first meridian, in accordance with the decision taken at Washington, is to be strictly enforced in practice. The introduction of international normal time, on the other hand, has had to be postponed, owing to insuperable practical difficulties connected with ordinary business life. In order to promote the project of any international survey of the entire globe, it is proposed to establish a Central Geodetic Office in Berlin.

THE Association for the Improvement of Geometrical Teaching has revised its "Syllabus of Elementary Geometrical Conics," and is about to publish the same, with three figures lettered in accordance with the enunciations of the Syllabus. The work will be interleaved to allow of teachers and students supplying their own proofs, and will, it is hoped, appear early in November. Messrs. Swan Sonnenschein are the publishers.

THE Bombay Government has just issued a long resolution on the subject of technical education, which is one of special importance to India. The resolution lays down the outlines of the scheme which it favours under three heads—agriculture, art, and mechanical industries. It proposes that the College of Science at Poonah should be a central institution for the teaching of higher agriculture, and that local classes and schools should be established throughout the province under the supervision of district officers and of the Educational Department. The Jamsetjee Jeejeebhoy School of Art in Bombay is to be the centre of Government efforts for the purpose of art teaching, and a report is called for as to the propriety of obtaining additional teaching. The question whether a technological institute for mechanical industries should be established is discussed at some length, and the Government expresses the opinion that the time for doing so has not yet come. Meanwhile, it is suggested that the Committee of the Ripon Memorial Fund should form itself into an association for promoting technical education in Bombay city, the Government promising to give it the utmost possible aid. The main dependence of other parts of the province must be upon the high schools for elementary science, and upon such institutions as may be started by means of local efforts. The resolution concludes by saying that the scheme is not academic, but that it is meant to enhance the well-being of the people at large by giving increased employment to labour and capital, and by cementing harmonious relations between them.

THE International Congress of Orientalists was opened at Vienna on the 27th inst., under the presidency of the Archduke Rénier. This is the seventh Congress of this body, the previous ones having been held at Paris in 1873, at London in 1874, St. Petersburg in 1876, Florence in 1878, Berlin in 1881, and Leyden in 1883. The Austrian Minister of Public Instruction welcomed the members, of whom there were about 300, in the name of the Government.

DR. SCHWEINFURTH has, in the interests of science, addressed to all Europeans, especially physicians, residing in Egypt, an inquiry as to whether, so far as they are aware, families of Northern origin settling in Egypt do, or do not, die out within three generations, or whether the race is capable of being perpetuated beyond that limit.

WE are requested to announce that the seventh annual Cryptogamic and Botanical Meeting of the Essex Field Club will be held on Friday and Saturday, October 15 and 16, in Epping Forest, the head-quarters for the day being at Buckhurst Hill. A large number of well-known botanists have promised to take part in the meeting, and the naming and arrangement of the specimens collected will be in the hands of Dr. Cooke, Rev. Canon Du Port, Dr. Wharton, Mr. Worthington Smith, and other fungologists. Botanists and others desirous of attending should communicate with the Hon. Secretary, Buckhurst Hill, Essex.

THE U.S. Hydrographic Office has received the following note:—"August 31, at 9.45 p.m., the steamer *City of Palatka*, Capt. Vögel, when a mile and a half north of Martin's industry lightship (off the coast, south of Charleston), in eight fathoms and a half of water, experienced a terrible rumbling sensation, lasting a minute and a half. There was quite a heavy sea from the south-east after leaving Charleston Bar at 5.30 p.m. When this rumbling sensation took place the wave-motion ceased. It was a perfect calm during the rumbling; after that the usual motion of the south-east swell took place. The wind at the time was south-west, light, weather cloudy, barometer 30·1, thermometer 80°. The sensation resembled a ship scraping a pebbly bottom, and the vibration of the ship was very great."

H.R.H. THE PRINCE OF WALES has decided that the Colonial and Indian Exhibition shall close on the evening of Wednesday, November 10.

WE hear that the first of the Grocers' "Medical Research Scholarships" has been awarded to Dr. Sims Woodhead, of Edinburgh. The value of the award is 250*l*.

"PHILIPS' Planisphere, showing the Principal Stars visible for every Hour in the Year" (London: George Philip and Son), is perhaps the best means yet devised of getting a preliminary acquaintance with the aspect of the sky. It consists of a movable disk representing the celestial sphere, and a fixed horizon corresponding to the latitude of London. On the edge of the disk are inscribed the signs of the zodiac, the months and days of the year; on the horizon, the hours of the day and night. By merely rotating the disk until any given day and hour are brought to coincide, the stars above the visible horizon of London at that time come into view. A continuance of the movement from east to west exhibits ten apparent revolutions of the stars. Each successive group on the chart rises and sets in its proper order, while its distance from the sun at any selected date can be estimated by following a line drawn from the celestial pole to the corresponding section of the disk. Its point of intersection with the ecliptic indicates the position of the sun. The same lines show the differences between solar and sidereal time throughout the year. A very little attention will enable the student to distinguish the circumpolar stars, to track the course of the Milky Way among the constellations, and to acquire some rough notion of the magnitudes of the principal stars. Quite a little stock of uranographical information, in short, is concentrated in this ingenious toy.

A CAREFUL revision of the hydrographic map of the Lake of Geneva has been lately made by M. Hornlimann, soundings being taken by the steel-wire method. It is shown that between Lutry, Ouchy, Evian, and La Tour-ronde the bottom of the lake is absolutely horizontal. For distances of 2 kilometres and more the differences of depth did not exceed 0·10 to 0·15 m. (being thus quite within the limits of observational error. The point of greatest depth was met with in the line which joins the mouth of the Flon, below Lausanne, and the church of Evian, 7 km. from the Swiss side and 5 from that of Savoy. This was 310 m. (say 1034 feet). The bottom of the lake is here about 219 feet above the sea.

THE earthquakes still continue in North America. Fresh shocks were felt at Charleston and other places in the south at five o'clock on the afternoons of the 27th and 28th inst. Shocks of earthquake were also at the same hour distinctly felt in Columbia, Augusta, and Savannah.

A SHARP shock of earthquake occurred at Constantinople at half-past four on the morning of the 26th inst., but no damage was done. At about a quarter to five on the same morning two sharp shocks in rapid succession were felt in Smyrna and the neighbourhood.

AN earthquake was felt at Aumale on the 22nd inst. at 11 a.m.; four shocks were reported.

THE White Island volcano, in the Bay of Plenty, off the North Island coast, New Zealand, is in active eruption, and sending forth a vast column of flame and smoke, rising to a height of 100 feet.

THE Ceylon branch of the Royal Asiatic Society has decided to print *in extenso* a translation of Prof. Virchow's monograph on the Veddas. An abridgment will appear in the forthcoming number of the Society's *Proceedings*.

FROM the Cambridge University Press the following new publications are announced:—"A History of the Theory of Elasticity and of the Strength of Materials, from Galilei to the Present Time," vol. i. "Galilei to Saint-Venant, 1639–1850," by the late I. Todhunter, D.Sc., F.R.S., edited and completed by Karl Pearson, M.A. "Lectures on the Physiology of Plants," by S. H. Vines, M.A., D.Sc., Fellow of Christ's College. "Travels in Northern Arabia in 1876 and 1877," by Charles M. Doughty, of Gonville and Caius College (with illustrations). "The Scientific Papers of the late Prof. J. Clerk Maxwell," edited by W. D. Niven, M.A.

MESSRS. CROSBY LOCKWOOD AND CO. announce the following books for the forthcoming season:—"Modern Engines and Boilers: Marine, Locomotive, and Stationary," by Walter S. Hutton, Civil and Mechanical Engineer (with upwards of 300 illustrations). "The Works' Manager's Hand-book of Modern Rules, Tables, and Data, for Civil and Mechanical Engineers, &c.," by Walter S. Hutton (third edition). "The Portable Engine, in Theory and Practice," by W. D. Wansbrough (with numerous illustrations). "Expansion of Structures by Heat," by John Keily, C.E., late Indian Public Works and Victorian Railway Departments. "Safe Railway Working," by Clement E. Stretton, C.E. "Drainage of Lands, Towns, and Buildings," a practical treatise, being an abridgment of the works of the late G. D. Dempsey, C.E., with extensive additions by D. Kinnear Clark, M.Inst.C.E. "Trusses of Wood and Iron: Practical Applications of Science in determining the Stresses, Breaking Weights, Safe Loads, Scantlings, and details of Construction," by William Griffiths. "Shoring and its Application," a manual for students, by George H. Blagrove (with numerous illustrations).

H. K. LEWIS has in preparation "An Introduction to Practical Bacteriology," by Edgar M. Crookshank, M.B. Lond., F.R.M.S., Demonstrator of Physiology, King's College, London (2nd edition); also, by the same author, "Photographs of Bacteria: an Investigation into the Value of Photography for delineating Preparations of Bacteria" (illustrated with 50 permanent autotypes and numerous wood engravings).

THE following publications are announced by Messrs. W. and R. Chambers:—"Natural History: its Rise and Progress in Britain, as developed in the Life and Labours of Leading Naturalists," by Prof. H. Alleyne Nicholson (Aberdeen). This will form vol. i. of a series called "Chambers's British Science Biographies," of which series the second volume, by Prof. Lapworth (Birmingham), will cover the field of British Geology. Other new books by the same publishers are: "Recent Travel and Adventure," with illustrations; and "Lessons in Elementary Dynamics," by H. G. Madan, M.A., Science Master in Eton College.

THE grease of sheep's wool, a substance hardly utilised hitherto, may now find use, according to a process lately brought before the French National Society of Agriculture by M. Robart. He finds that, brought to its point of fusion, it very readily absorbs certain sulphur-compounds; thus it will fix as much as 100 times its volume of sulphuretted hydrogen; and so treated it becomes saponifiable in the cold state. M. Rohart presented some excellent soap made from the grease. The operation required takes less than an hour, whereas soaps with a base of soda generally take 6 to 8 hours in their production. Moreover, the saponification can be obtained completely without caustic alkalies, and simply with alkaline carbonates; a new scientific fact, applicable to all fatty matters when sulphurised. Thus a great economy is possible. This sulphurised soap is recommended by M. Rohart, *inter alia*, for use in vine-cultivation.

IN a recent thesis on the modification of plants by climate, Mr. Crozier, of Michigan University, considers it established "that as plants move from the locality of their largest development towards their northern limit of growth, they become dwarfed in habit, are rendered more fruitful, and all parts become more highly coloured, Their comparative leaf surface is often increased, their form modified, and their composition changed. Their period of growth is also shortened, and they are enabled to develop at a lower temperature."

THE successful cultivation, since 1884, of the Ramie or China grass plant (*Boehmeria nivea*) on the Champ-de-l'Air at Lausanne (altitude 520 m.), by Prof. Schnetzler, is an interesting fact in botany. This shrub, a native of China and Sumatra, has been grown in the south of the United States and of France for thirty years. Recently it has been introduced into Algeria. There is of course a striking difference in the conditions of temperature between Lausanne and the places in Asia where Ramie is grown. While the latitude of the latter is from 15° to 35°, that of Lausanne is 46° 31′. The mean temperature at Lausanne is 9°·5 C. Last winter the plants underwent long periods of great cold; in one case, *e.g.*, the thermometer being below zero for 124 hours, with a minimum on the ground of −12°·5 C.

THE question of telephony *v.* telegraphy has been recently discussed by a well-known German electrician, Dr. Wietlisbach. The chief hindrance to the use of the telephone for long distances is, he points out, of a financial, not of a technical, nature. A telephone-line 2000 km. long costs considerably over a million marks. It is still possible to speak very well this distance; but even supposing the line were in constant use day and night, the receipts must be 5 marks (say shillings) a minute to make it pay. In telephone work, however, the line is in use only a few hours daily; hence a short conversation would cost at least 50 marks (2*l.* 10*s.*). That is, of course, too dear for ordinary traffic. The telegraph works, with almost the same speed, more than ten times more cheaply. Thus the question as to rivalry between telephone and telegraph finds its settlement. The telephone, up to about 500 km. distance (say 310 miles), will more and more displace the telegraph, and find an extension which the telegraph would never reach. But for greater distances the telegraph must keep the upper hand. Thus telephone and telegraph are really not rivals, but fitted to supplement each other.

WE have received the report for the past year of the School of Mines, Ballaarat, an institution which its Council believe is in a fair way of becoming the leading School of Science in the colony of Victoria. The increasing number of the students who avail themselves of the constantly extending opportunities for instruction offered by the School renders additional teaching power a necessity, and this requires, first of all, an increased income. It is to be hoped that the Council have been successful in its request for double the present annual subsidy from the Government. A School of Mines is perhaps the most immediately useful and paying one a young community can have. A new and enlarged museum has been added to the School, and Mr. Oddie, the Vice-President, has undertaken at his own expense to erect and equip an astronomical observatory. Two rooms, each 16 feet by 18, were erected when the report was drafted, and in one of these a 12½-inch Newtonian reflector has been placed in position. The second room is to be utilised for spectrum analysis, solar physics, testing specula, &c. A system of meteorological observations with the latest instruments, in connection with the Melbourne Observatory, has also been introduced. A recent task of the School authorities, in which many of our readers may be presumed to be interested, is the collection of rocks and minerals representing the geology of Western Victoria in the Colonial and Indian Exhibition. At the close of the Exhibition it will be presented to the Museum of the Geological Survey of Great Britain. The reports of the individual professors show progress in almost every direction—in the number of students, of subjects taught, and of average attendances of each student. We observe that the benefits of the School are largely extended by means of a concession from the Government railways permitting students to travel over long distances at exceedingly low fares. This is one of those concessions which cost so little, yet are worth so much, and which are more common in the United States or the colonies than they are in England.

IN a very interesting paper contributed to the *Bulletin* of the Essex Institute of Salem, Mr. A. McFarland Davis writes on some of the games of the Indian tribes of North America. Several of these are described at considerable length, mostly from the early Jesuit records. Lacrosse is the first and most important of these; it was, as it is now, purely a game of skill, but it was a contest of grave importance, not a mere pastime, and was domesticated over a wide extent of territory. Another very widely-spread game was "platter," which was played with dice, and was wholly a game of chance; the third was a game of chance and skill combined, and in some of its forms was exceedingly complicated. It was called "straws," because a bundle of straws was divided, the game turning on the odd or even numbers in the heaps. It resembles the celebrated Chinese game of *fantan*, which forms one of the principal sources of revenue of one European colony in the East. Sundry other games not so widely spread as these are also described by Mr. Davis. The extraordinary importance attached to these games, the strange and solemn ceremonies with which they were frequently initiated, give them an interest in the eyes of anthropologists beyond that of mere curiosity.

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus*) from India, presented by Mrs. Faulkner; two Golden Eagles (*Aquila chrysaetos*) from the Isle of Mull, Argyllshire, Scotland, presented by His Grace the Duke of Argyll, K.G., F.Z.S.; a Stock Dove (*Columba œnas*), British, presented by Mr. Charles Whymper, F.Z.S.; an Anaconda (*Eunectes murinus*) from South America, deposited; a Lesser White-nosed Monkey (*Cercopithecus petaurista*) from West Africa, purchased; a Maned Goose (*Bernicla jubata*) from Australia, received in exchange; a Spotted Hyæna (*Hyæna crocuta*), born in the Gardens.

OUR ASTRONOMICAL COLUMN

STELLAR PHOTOMETRY.—Mr. Chandler, of Cambridge, U.S., presented an interesting and important paper to the Section of Mathematics and Astronomy of the American Association at the recent meeting, the title being "A Comparative Estimate of Methods and Results in Stellar Photometry." According to the account of the paper given in *Science* (vol. viii., No. 187), Mr. Chandler took for his text the general statement that instrumental photometry had thus far proved a failure; that is, it had not developed a more uniform scale than Argelander's, nor had the accuracy of individual determinations been increased, but they were, on the contrary, far more uncertain than the old differential naked-eye estimates. In support of his views Mr. Chandler showed that, for stars of Argelander's scale between magnitudes 2 and 6, the photometric catalogues of Seidel, Peirce, Wolf, Pickering, and Pritchard differed among themselves as much in their measures of what Argelander called a difference of one magnitude, as they did in their measures of his successive magnitudes. Their average values of the logarithm of the light-ratio for one of Argelander's magnitudes between 2 and 6, ranged between ·30 and ·38, about ·35 for the mean of all the above-mentioned catalogues. Between magnitudes 6 and 9 of Argelander's scale, the catalogues of Rosén and Ceraski averaged about ·35 for the light-ratio, while Pickering's late results with the meridian photometer gave (between magnitudes 6 and 8·5) ·48 instead of ·35 for this ratio. Coming to accidental errors, Mr. Chandler showed that, from a discussion of the naked-eye estimates of Gould, Sawyer, and himself, the probable error of a single estimate was a little over ± ·06 of a magnitude when the stars were at considerable distances from each other, and about ± ·05 of a magnitude when near; while the probable error of a single measure in the "Harvard Photometry" was ± ·17 of a magnitude, and in the "Uranometria Oxoniensis" about ± ·10 of a magnitude. The large residuals in the "Harvard Photometry" appear to arise, according to Mr. Chandler, from the wrong identification of stars in many cases, one instance being cited where no bright star exists in or near the place given in the observing-list, on account of a misprint in the *Durchmusterung*, and yet some neighbouring star was observed on several nights for it. The author, in conclusion, pointed out that we must obtain better results from photometers if we ever expect to use their results for the detection or measurement of variable stars, since several variables have been detected, and their periods and light curves well determined by eye-estimates, whose whole range of variation is no greater than the whole range of error in the photometric observations upon a single star with the meridian photometer.

A NEW OBSERVATORY IN LA PLATA.—In the *Bulletin Astronomique*, tome iii. Août 1886, M. Mouchez gives an account of a new Observatory which is being built in the town of La Plata. The Observatory appears to have a remarkably good instrumental equipment, including a telescope of 0·80m. aperture, an "équatorial coudé" of 0·43m. aperture, a meridian instrument of 0·22m. aperture, an apparatus for celestial photography of the same dimensions as that of MM. Henry at the Paris Observatory, a Thollon spectroscope with objective of 0·25m. aperture, besides a collection of geodetical instruments. The new Observatory is under the direction of M. Beuf, lately an officer in the French Navy, and his first efforts are to be directed towards the carrying out of a geodetic survey of the vast territory of the province, including the measurement of an extensive meridian arc in the plains of Chaco and Patagonia. The measurement of this arc will supply a want which has been long felt by geodesists, and will give new and valuable data for an increase in our knowledge of the terrestrial spheroid. He trusts that M. Beuf will be successful in this arduous and important undertaking, and also that he will have sufficient energy, and be supplied with a sufficient staff of observers, to work to advantage the numerous and powerful instruments which the Observatory possesses.

HELIOMETRIC OBSERVATIONS OF THE PLEIADES.—In the note on this subject, printed in last week's "Astronomical Column," the words "since 1860" should read "since 1840," the latter being the date of Bessel's determinations resulting from his observations with the Königsberg heliometer made during the years 1829-41.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1886 *OCTOBER* 3–9

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on October 3

Sun rises, 6h. 6m.; souths, 11h. 49m. 1·7s.; sets, 17h. 32m.; decl. on meridian, 4° 2′ S.: Sidereal Time at Sunset, 18h. 21m.

Moon (at First Quarter October 4) rises, 12h. 26m.; souths, 16h. 54m.; sets, 21h. 20m.; decl. on meridian, 18° 28′ S.

Meteor Showers

The coming week is usually a somewhat less fruitful one for meteors than the one just past. The *Arietids*, October 7, R.A. 31°, Decl. 9° N., form the principal shower; a radiant in Musca, R.A. 46°, Decl. 26° N., and another near Polaris, R.A. 133°, Decl. 79° N., are also active at this time.

METEORITES, METEORS, AND SHOOTING-STARS[1]

YOU are kindly giving to me an hour to-night in which I may speak to you. I do not have enough confidence in myself to justify me in speaking to such an audience as this upon one of those broad subjects that belong equally to all Sections of the Association. The progress, the encouragements, and the difficulties in each field are best known to the workers in the field, and I should do you little good by trying to sum up and recount them. Let me rather err, then, if at all, by going to the opposite extreme.

Two years ago your distinguished President instructed and delighted us all by speaking of the pending problems of astronomy, what they are, and what hopes we have of solving them. To one subject in this one science, a subject so subordinate that he very properly gave it only brief notice, I ask your attention. I propose to state some propositions which we may believe to be probably true about the meteorites, the meteors, and the shooting-stars.

In trying to interest you in this subject, so remote from the studies of most of you, I rely upon your sense of the unity of all science, and at the same time upon the strong hold which these weird bodies have ever had upon the imaginations of men. In ancient times temples were built over the meteorite images that fell down from Jupiter, and divine worship was paid them; and in these later days a meteorite stone that fell last year in India became the object of daily anointings and other ceremonial worship. In the fearful imagery of the Apocalypse, the terrors are deepened by there falling "from heaven a great star burning as a torch," and by the stars of heaven falling "unto the earth as a fig tree casteth her unripe figs when she is shaken of a great wind." The "great red dragon having seven heads and ten horns, and upon his head seven diadems," is presented in the form of a huge fire-ball. "His tail draweth the third part of the stars of heaven, and did cast them to the earth." Records of these feared visitors, under the name of flying dragons, are found all through the pages of the monkish chroniclers of the Middle Ages. The Chinese appointed officers to record the passage of meteors and comets, for they were thought to have somewhat to say to the weal or woe of rulers and people.

By gaining in these later days a sure place in science, these bodies have lost their terrors; but so much of our knowledge about them is fragmentary, and there is still so much that is mysterious, that men have loved to speculate about their origin, their functions, and their relations to other bodies in the solar system. It has been easy, and quite common too, to make these bodies the cause of all kinds of things for which other causes could not be found.

They came from the moon; they came from the earth's volcanoes; they came from the sun; they came from Jupiter and the other planets; they came from some destroyed planet; they came from comets; they came from the nebulous mass from which the solar system has grown; they came from the fixed stars; they came from the depths of space.

They supply the sun with his radiant energy; they give the moon her accelerated motion; they break in pieces heavenly bodies; they threw up the mountains on the moon; they made large gifts to our geological strata; they cause the auroras; they give regular and irregular changes to our weather.

A comparative geology has been built up from the relations of the earth's rocks to the meteorites; a large list of new animal forms have been named from their concretions; and the possible origin of life in our planet has been credited to them.

They are satellites of the earth; they travel in streams, and in groups, and in isolated orbits about the sun; they travel in groups and singly through stellar spaces; it is they that reflect the zodiacal light; they constitute the tails of comets; the solar corona is due to them; the long coronal rays are meteor streams seen edgewise.

Nearly all of these ideas have been urged by men deservedly of the highest repute for good personal work in adding to human knowledge. In presence of this host of speculations it will not, I hope, be a useless waste of your time to inquire what we may reasonably believe to be probably true. And if I shall have no new hypotheses to give you, I offer as my excuse that nearly all possible ones have been already put forth. This Association exists, it is true, for the advancement of science, but science may be advanced by rejecting bad hypotheses as well as by framing good ones.

I begin with a few propositions about which there is now practical unanimity among men of science. Such propositions need only be stated. The numbers that are to be given express quantities that are open to revision and moderate changes.

(1) The luminous meteor tracks are in the upper part of the earth's atmosphere. Few, if any, appear at a height greater than one hundred miles, and few are seen below a height of thirty miles from the earth's surface, except in rare cases where stones and irons fall to the ground. All these meteor tracks are caused by bodies which come into the air from without.

(2) The velocities of the meteors in the air are comparable with that of the earth in its orbit about the sun. It is not easy to determine the exact values of those velocities, yet they may be roughly stated as from fifty to two hundred and fifty times the velocity of sound in the air, or of a cannon-ball.

(3) It is a necessary consequence of these velocities that the meteors move about the sun and not about the earth as the controlling body.

(4) There are four comets related to four periodic star-showers that come on the dates April 20, August 10, November 14, and November 27. The meteoroids which have given us any one of these star-showers constitute a group, each individual of which

[1] Address to the American Association for the Advancement of Science, at Buffalo, August 18, 1886, by Prof. H. A. Newton, of New Haven, the retiring President of the Association.

moves in a path which is like that of the corresponding comet. The bodies are, however, now too far from one another to influence appreciably each other's motions.

(5) The ordinary shooting-stars in their appearance and phenomena do not differ essentially from the individuals in star-showers.

(6) The meteorites of different falls differ from one another in their chemical composition, in their mineral forms, and in their tenacity. Yet through all these differences they have peculiar common properties which distinguish them entirely from all terrestrial rocks.

(7) The most delicate researches have failed to detect any trace of organic life in meteorites.

These propositions have practically universal acceptance among scientific men. We go on to consider others which have been received with hesitation, or in some cases have been denied.

With a great degree of confidence, we may believe that shooting-stars are solid bodies. As we see them they are discrete bodies, separated even in prolific star-showers by large distances one from another. We see them penetrate the air many miles, that is, many hundred times their own diameters at the very least. They are sometimes seen to break in two. They are sometimes seen to glance in the air. There is good reason to believe that they glance before they become visible.

Now these are not the phenomena which may be reasonably expected from a mass of gas. In the first place a spherical mass of matter at the earth's distance from the sun, under no constraint, and having no expansive or cohesive power of its own, must exceed in density air at one-sixth of a millimetre pressure (a density often obtained in the ordinary air-pump), or else the sun by his unequal attraction for its parts will scatter it. Can we conceive that a small mass of gas with no external restraint to resist its elastic form, can maintain so great a density?

But suppose that such a mass does exist, and that its largest and smallest dimensions are not greatly unequal; and suppose further that it impinges upon the air with a planetary velocity; could we possibly have as the visible result a shooting-star? When a solid meteorite comes into the air with a like velocity, its surface is burned or melted away. Iron masses and many of the stones have had burned into them those wonderful pittings or cupules which are well imitated, as M. Daubrée has shown, by the erosion of the interior of steel cannon by the continuous use of powder under high pressure. They are imitated also by the action of dynamite upon masses of steel near which the dynamite explodes. Such tremendous resistance that mass of gas would have to meet! The first effect would be to flatten the mass, for it is elastic; the next to scatter it, for there is no cohesion. We ought to see a flash instead of a long burning streak of light. The mass that causes the shooting-star can hardly be conceived of except as a solid body.

Again, we may reasonably believe that the bodies that cause the shooting-stars, the large fire-balls, and the stone-producing meteor, all belong to one class. They differ in kind of material, in density, in size. But from the faintest shooting-star to the largest stone-meteor, we pass by such small gradations that no clear dividing lines can separate them into classes. See wherein they are alike:—

(1) Each appears as a ball of fire traversing the apparent heavens, just as a single solid but glowing or burning mass would do.

(2) Each is seen in the same part of the atmosphere, and moves through its upper portion. The stones come to the ground, it is true, but the luminous portion of their paths generally ends high up in the air.

(3) Each has a velocity which implies an orbit about the sun.

(4) The members of each class have apparent motions which imply common relations to the horizon, to the ecliptic, and to the line of the earth's motion.

(5) A cloudy train is sometimes left along the track, both of the stone-meteor, and of the shooting-star.

(6) They have like varieties of colours, though in small meteors they are naturally less intense and are not so variously combined as in large ones.

In short, if the bodies that produce the various kinds of fire-balls had just the differences in size and material which we find in meteorites, all the differences in the appearances would be explained; while, on the other hand, a part of the likenesses that characterise the flights point to something common in the astronomical relations of the bodies that produce them.

This likeness of the several grades of luminous meteors has not been admitted by all scientific men. Especially it was not accepted by your late President, Prof. J. Lawrence Smith, who by his studies added so much to our knowledge of the meteorites. The only objection, however, so far as I know, that has been urged against the relationship of the meteorites and the star-shower meteors, and the only objection which I have been able to conceive of that has apparent force is the fact that no meteorites have been secured that are known to have come from the star-showers. This objection is plausible, and has been urged, both by mineralogists and astronomers, as a perfect reply to the argument for a common nature to all the meteors.

But what is its real strength? There have been in the last hundred years five or six star-showers of considerable intensity. The objection assumes that if the bodies then seen were like other meteors we should have reason to expect that among so many hundreds of millions of individual flights a large number of stones would have come to the ground and have been picked up.

Let us see how many such stones we ought to expect. A reasonable estimate of the total number of meteors in all of these five or six star-showers combined makes it about equal to the number of ordinary meteors which come into the air in six or eight months. Inasmuch as we can only estimate the numbers seen in some of the showers, let us suppose that the total number for all the star-showers was equal to one year's supply of ordinary meteors. Now the average annual number of stone-meteors of known date from which we have secured specimens has, during this hundred years, been about two and a half.

Let us assume, then, that the luminous meteors are all of like origin and astronomical nature; and further assume that the proportion of large ones, and of those fitted to come entirely through the air without destruction, is the same among the star-shower meteors as among the other meteors. With these two assumptions, a hundred years of experience would then lead us to expect two, or perhaps three, stone falls from which we secure specimens during all the half-dozen star-showers put together. To ask for more than two or three is to demand of star-shower meteors more than other meteors give us. The failure to get these two or three may have resulted from chance, or from some peculiarity in the nature of the rocks of Biela's and Tempel's comets. It is very slender ground upon which to rest a denial of the common nature of objects that are so similar in appearance and behaviour as the large and small meteors.

It may be assumed, then, as reasonable that the shooting-stars and the stone-meteors, together with all the intermediate forms of fire-balls, are like phenomena. What we know about the one may with due caution be used to teach facts about the other. From the mineral and physical nature of the different meteorites, we may reason to the shooting-stars, and from facts established about the shooting-stars we may infer something about the origin and history of the meteorites. Thus it is reasonable to suppose that the shooting-stars are made up of such matter and such varieties of matter as are found in meteorites. On the other hand, since star-showers are surely related to comets, it is reasonable to look for some relation of the meteorites to the astronomical bodies and systems of which the comets form a part.

This common nature of the stone-meteor and the shooting-stars enables us to get some idea, indefinite but yet of great value, about the masses of the shooting-stars. Few meteoric stones weigh more than 100 lbs. The most productive stone-falls have furnished only a few hundred pounds each, though the irons are larger. Allowing for fragments not found, and for portions scattered in the air, such meteors may be regarded as weighing a ton, or it may be several tons, on entering the air. The explosion of such a meteor is heard a hundred miles around, shaking the air and the houses over the whole region like an earthquake. The size and brilliancy of the flame of the ordinary shooting-star is so much less than that of the stone-meteor that it is reasonable to regard the ordinary meteoroid as weighing pounds, or even ounces, rather than tons.

Determinations of mass have been made by measuring the light and computing the energy needed to produce the light. These are to be regarded as lower limits of size, because a large part of the energy of the meteors is changed into heat and motion of the air. The smaller meteors visible to the naked eye may be thought of without serious error as being of the size of gravel stones, allowing, however, not a little latitude to the meaning of the indefinite word "gravel."

These facts about the masses of shooting-stars have important

consequences. The meteors, in the first place, are not the fuel of the sun. We can measure and compute within certain limits of error the radiant energy emitted by the sun. The meteoroids large enough to give shooting-stars visible to the naked eye are scattered very irregularly through the space which the earth traverses; but in the mean each is distant two or three hundred miles from its near neighbours. If these meteoroids supply the sun's radiant energy, a simple computation shows that the average shooting-star ought to have a mass enormously greater than is obtained from the most prolific stone-fall.

Moreover, if these meteoroids are the source of the solar heat, their direct effect upon the earth's heat by their impact upon our atmosphere ought also to be very great: whereas the November star-showers, in some of which a month's supply of meteoroids was received in a few hours, do not appear to have been followed by noticeable increase of heat in the air.

Again, the meteoroids do not cause the acceleration of the moon's mean motion. In various ways the meteors do shorten the month as measured by the day. By falling on the earth and on the moon they increase the masses of both, and so make the moon move faster. They check the moon's motion, and so, bringing it nearer to the earth, shorten the month. They load the earth with matter which has no momentum of rotation, and so lengthen the day. The amount of matter that must fall upon the earth in order to produce in all these ways the observed acceleration of the moon's motion, has been computed by Prof. Oppolzer. But his result would require for each meteoroid an enormous mass, one far too great to be accepted as possible.

Again, the supposed power of such small bodies,—bodies so scattered as these are, even in the densest streams,—to break up the comets or other heavenly bodies, and also their power, by intercepting the sun's rays, to affect our weather, must, in absence of direct proof to the contrary, be regarded as insignificant. So, too, their effect in producing geologic changes by adding to the earth's strata has, without doubt, been very much over-estimated. During a million of years, at the present rate of, say, 15,000,000 of meteors per day, there comes into the air about one shooting-star or meteor for each square foot of the earth's surface.

To assume a sufficient abundance of meteors in ages past to accomplish any of these purposes is, to say the least, to reason from hypothetical and not from known causes. The same may be said of the suggestion that the mountains of the moon are due to the impact of meteorites. Enormously large meteoroids in ages past must be arbitrarily assumed, and, in addition, a very peculiar plastic condition of the lunar substance, in order that the impact of a meteoroid can make in the moon depressions ten, or fifty, or a hundred miles in diameter, surrounded by abrupt mountain walls two, and three, and four miles high, and yet the mountain walls not sink down again.

The known visible meteors are not large enough nor numerous enough to do the various kinds of work which I have named. May we not assume that an enormous number of exceedingly small meteoroids are floating in space, are falling into the sun, are coming into our air, are swept up by the moon? May we not assume that some of these various results, which cannot be due to meteoroids large enough for us to see as they enter the air, may be due to this finer impalpable cosmic dust? Yes, we may make such an assumption. There exist, no doubt, multitudes of these minute particles travelling in space. But science asks not only for a true cause, but a sufficient cause. There must be enough of this matter to do the work assigned to it. At present we have no evidence that the total existing quantity of such fine material is very large. It is to be hoped that through the collection and examination of meteoric dust we may soon learn something about the amount which our earth receives Until that shall be learned, we can reason only in general terms. So much matter coming into our atmosphere as these several hypotheses require would, without doubt, make its presence known to us in the appearance of our sunset skies and in a far greater deposit of meteoric dust than has ever yet been proven.

A meteoroid origin has been assigned to the light of the solar corona. It is not unreasonable to suppose that the amount of the meteoroid matter should increase toward the sun, and that the illumination of such matter would be much greater near the solar surface. But it is difficult to explain upon such an hypothesis the radial structure, the rifts, and the shape of the curved lines, that are marked features of the corona. These seem to be inconsistent with any conceivable arrangement of meteoroids in the vicinity of the sun. If the meteoroids are arranged at random, there should be a uniform shading away of light as we go from the sun. If the meteoroids are in streams along cometary orbits, all lines bounding the light and shade in the coronal light should evidently be projections of conic sections of which the sun's centre is the focus. There are curved lines in abundance in the coronal light, but, as figured by observers and in the photographs, they seem to be entirely unlike such projections of conic sections. Only by a violent treatment of the observations can the curves be made to represent such projections. They look as though they were due to forces at the sun's surface rather than at his centre. If those complicated lines have any meteoroid origin (which seems very unlikely), they suggest the phenomena of comets' tails rather than meteoroid streams or sporadic meteors. The hypothesis that the long rays of light which sometimes have been seen to extend several degrees from the sun at the time of the solar eclipse are meteor streams seen edgewise, seems possibly true, but not at all probable.

The observed life of the meteor is only a second, or at most a few seconds, except when a large one sends down stones to remain with us. What can we learn about its history and origin?

Near the beginning of this century, when small meteors were looked on as some form of electricity, the meteorites were very generally regarded as having been thrown out from the lunar volcanoes. But as the conviction gained place that the meteorites moved not about the earth, but about the sun, it was seen that the lunar volcanoes must have been very active to have sent out such an enormous number of stones as are needed, in order that we should so frequently encounter them. When it was further considered that there is no proof that lunar volcanoes are now active, and that when they were active they were more likely to have been open seas of lava, not well fitted to shoot out such masses, the idea of the lunar origin of the meteorites gradually lost ground.

But the unity of meteorites with shooting-stars, if true, increases a hundredfold the difficulty, and would require that the comets have the same origin with the meteorites. No one claims that the comets came from the moon.

That the meteorites came from the earth's volcanoes is still held by some men of science, particularly by the distinguished Astronomer-Royal for Ireland. The difficulties of the hypothesis are, however, exceedingly great. In the first place, the meteorites are not like terrestrial rocks. Some minerals in them are like minerals in the rocks. Some irons are like the Greenland terrestrial irons. But no rock in the earth has yet been found that would be mistaken for a meteorite of any one of the two or three hundred known stone-falls. The meteorites resemble the deep terrestrial rocks in some particulars, it is true, but the two are also thoroughly unlike.

The terrestrial volcanoes must also have been wonderfully active to have sent out such a multitude of meteorites as will explain the number of stone-falls which we know, and which we have good reason to believe, have occurred. The volcanoes must also have been wonderfully potent. The meteorites come to us with planetary velocities. In traversing the thin upper air they are burned and broken by the resisting medium. Long before they have gone through the tenth part of the atmosphere the meteorites usually are arrested and fall to the ground. If these bodies were sent out from the earth's volcanoes, they left the upper air with the same velocity with which they now return to it. What energy must have been given to the meteorite before it left the volcano, to make it traverse the whole of our atmosphere and go away from the earth with a planetary velocity. Is it reasonable to believe that volcanoes were ever so potent, or that the meteorites would have survived such a journey?

No one claims that the meteors of the star-showers, or their accompanying comet, came from the earth's volcanoes. To ascribe a terrestrial origin to meteorites is, then, to deny the relationship of the shooting-star and the stone-meteor. Every reason for their likeness is an argument against the terrestrial origin of the stones. To suppose that the meteors came from any planets that have atmospheres involves difficulties not unlike to, and equally serious with, those involved in the theory of a terrestrial origin.

The solar origin of meteorites has been seriously urged, and deserves a serious answer. The first difficulty which this hypothesis meets is that solid bodies should come from the hot sun.

Besides this, they must have passed without destruction through an atmosphere of immense thickness. Then there is a geometric difficulty. The meteorite shot out from the sun would travel, under the law of gravitation, nearly in a straight line out and back again into the sun. If in its course it enters the earth's atmosphere, its relative motion—that which we see—should be in a line parallel to the ecliptic, except as slightly modified by the earth's attraction. A large number of these meteors, that is, most if not all well-observed fire-balls, have certainly not travelled in such paths. These did not come from the sun.

It has been a favourite hypothesis that the meteorites came from some planet broken in pieces by an internal catastrophe. There is much which mineralogists can say in favour of such a view. The studies of M. Stanislas Meunier and others into the structure of meteorites have brought out many facts which make this hypothesis plausible. It requires, however, that the stone-meteor be not regarded as of the same nature as the star-shower meteor, for no one now seriously claims that the comets are fragments of a broken planet. The hypothesis of the existence of such a planet is itself arbitrary; and it is not easy to understand how any mass that has become collected by the action of gravity and of other known forces should, by internal forces, be broken in pieces, and these pieces sent asunder. The disruption of such a planet by internal forces, after it has by cooling lost largely its original energy, would be specially difficult to explain.

We cannot, then, look to the moon, nor to the earth, nor to the sun, nor to any of the large planets, nor to a broken planet, as the first home of the meteoroids, without seeing serious if not insuperable objections. But since some of them were in time past certainly connected with comets, and since we can draw no line separating shooting-stars from stone-meteors, it is most natural to assume that all of them are of a cometary origin. Are there any insuperable objections that have been urged against the hypothesis that all of the meteoroids are of like nature with the comets, that they are in fact fragments of comets, or it may be sometimes minute comets themselves? If such objections exist, they ought evidently to come mainly from the mineralogists, and from what they find in the internal structure of the meteorites. Astronomy has not as yet furnished any objections. It seems strange that comets break in pieces, but astronomers admit it, for it is an observed fact. It is strange that groups of these small bodies should run before and follow after comets along their paths, but astronomers admit it as fact in the case of at least four comets. Astronomically there would seem to be no more difficulty in giving such origin to the sporadic meteor, and to the large fire-ball, and to the stone-meteor, than there is in giving it to the meteor of the star-shower. If, then, the cometic origin of meteorites is inadmissible, the objections must come mainly from the nature and structure of the meteoric stones and irons. Can the comet in its life and history furnish the varied conditions and forces necessary to the manufacture or growth of these peculiar structures?

It is not necessary, in order to answer this question, to solve the thousand puzzling problems that can be raised about the origin and the behaviour of comets. Comets exist in our system, and have their own peculiar development, whatever be our theories about them. It will be enough for my present purpose to assume as probably true the usual hypothesis that they were first condensed from nebulous matter; that that matter may have been either the outer portions of the original solar nebula, or matter entirely independent of our system and scattered through space. In either case, the comet is generally supposed, and probably must be supposed, to have become aggregated far away from the sun. This aggregation was not into one large body, to be afterwards broken up by disruption or by solar action. The varieties of location of the cometic orbits seem inexplicable upon any such hypothesis. Separate centres of condensation are to be supposed, but they are not *a priori* unreasonable. This is the rule rather than the exception everywhere in Nature.

Assume, then, such a separate original condensation of the comet in the cold of space, and that the comet had a very small mass compared with the mass of the planets. Add to this the comet's subsequent known history, as we are seeing it in the heavens. Have we therein known forces and changes and conditions of such intensity and variety as the internal structure of the meteorites calls for? What that structure is, and, to some extent, what conditions must have existed at the time and place of its first formation, and during its subsequent transformations, mineralogists rather than astronomers must tell us. For a long time it was accepted without hesitation that these bodies required great heat for their first consolidation. Their resemblance to the earth's volcanic rocks was insisted on by mineralogists. Prof. J. Lawrence Smith, in 1855, asserted without reserve that "they have all been subject to a more or less prolonged igneous action corresponding to that of terrestrial volcanoes." Director Haidinger, in 1861, said, "With our present knowledge of natural laws, these characteristically crystalline formations could not possibly have come into existence except under the action of high temperature combined with powerful pressure." The likeness of these stones to the deeper igneous rocks of the earth, as shown by the experiments of M. Daubrée, strengthened this conviction. Mr. Sorby, in 1877, said, "It appears to me that the conditions under which meteorites were formed must have been such that the temperature was high enough to fuse stony masses into glass; that the particles could exist independently one of the other in an incandescent atmosphere subject to violent mechanical disturbances; that the force of gravitation was great enough to collect these fine particles together into solid masses, and that these were in such a situation that they could be metamorphosed, further broken up into fragments, and again collected together."

Now, if meteorites could come into being only in a heated place, then the body in which they were formed ought, it would seem, to have been a large one. But the comets, on the contrary, appear to have become aggregated in small masses. The idea that heat was essential to the production of these minerals was at first a natural one. All other known rock-formations are the result of processes that involve water or fire or metamorphism. All agree that the meteorites could not have been formed in the presence of water or free oxygen. What conclusion was more reasonable than that heat was present in the form of volcanic or of metamorphic action?

The more recent investigations of the meteorites and kindred stones, especially the discussions of the Greenland native irons and the rocks in which they were embedded, are leading mineralogists, if I am not mistaken, to modify their views. Great heat at the first consolidation of the meteoric matter is not considered so essential. In a late paper M. Daubrée says:—"It is extremely remarkable that, in spite of their great tendency to a perfectly distinct crystallisation, the silicate combinations which make up the meteorites are there only in the condition of very small crystals, all jumbled together as if they had not passed through fusion. If we may look about us for something analogous, we should say that, instead of calling to mind the long needles of ice which liquid water forms as it freezes, the fine-grained texture of meteorites resembles rather that of hoar-frost, and that of snow, which is due, as is known, to the immediate passage of the atmospheric vapour of water into the solid state." So Dr. Reusch, from the examination of the Scandinavian meteorites, concludes that "there is no need to assume volcanic and other processes taking place upon a large heavenly body formerly existing, but which has since gone to pieces."

The meteorites resemble the lavas and slags on the earth. These are formed in the absence of water, and with a limited supply of oxygen, and heat is present in the process. But is heat necessary? Some crystallisations do take place in the cold; some are direct changes from gaseous to solid forms. We cannot in the laboratory reproduce all the conditions of crystallisation in the cold of space. We cannot easily determine whether the mere absence of oxygen will not account fully for the slag-like character of the meteorite minerals. Wherever crystallisation can take place at all, if there is present silicon and magnesium and iron and nickel, with a limited supply of oxygen, there silicates ought to be expected in abundance, and the iron and nickel in their metallic form. Except for the heat, the process should be analogous to that of the reduction of iron in the Bessemer cupola, where the limited supply of oxygen combines with the carbon and leaves the iron free. The smallness of the comets, should not, then, be an objection to considering the meteoric stones and irons as pieces of comets. There is no necessity of assuming that they were parts of a large mass, in order to provide an intensely heated birth-place.

But although great heat was not needed at the first formation, there are many facts about these stones which imply that violent forces have in some way acted during the meteorites' history. The brecciated appearance of many specimens, the fact that the fragments in a breccia are themselves a finer breccia, the frac-

tures, infiltrations, and apparent faultings seen in microscopic sections and by the naked eye—these all imply the action of force. M. Daubrée supposes that the union of oxygen and silicon furnishes sufficient heat for making these minerals. If this is possible, those transformations may have taken place in their first home. Dr. Reusch argues that the repeated heating and cooling of the comet, as it comes down to the sun and goes back again into the cold, is enough to account for all the peculiarities of structure of the meteorites. These two modes of action do not, however, exclude each other. Suppose, then, a mass containing silicon, magnesium, iron, nickel, a limited supply of oxygen, and small quantities of other elements, all in their primordial or nebulous state (whatever that may be), segregated somewhere in the cold of space. As the materials consolidate or crystallise, the oxygen is appropriated by the silicon and magnesium, and the iron and nickel are deposited in metallic form. Possibly the heat developed may, before it is radiated into space, modify and transform the substance. The final result is a rocky mass (or possibly several adjacent masses), which sooner or later is no doubt cooled down throughout to the temperature of space. This mass, in its travels, comes near to the sun. Powerful action is there exerted upon it. It is heated. How intense is that heat upon a cold rock, unprotected apparently by its thin atmosphere, it is not possible to say. We know that the sun's action is strong enough to develop that immense train, the comet's tail, that sometimes spans our heavens. It is broken in pieces. We have seen the portions go off from the sun, to come back, probably, as separate comets. Solid fragments are scattered from it to travel in their own independent orbits. What is the condition of the burnt and crackled surface of a cometic mass or fragment as it goes out from the sun again into the cold? What changes may not that surface undergo before it comes back again, to pass anew through the fiery ordeal? We have here forces that we know are acting. They are intense, and act under varied conditions. The stones subject to those forces can have a history full of all the scenes and actions required for the growth of such strange bodies as have come down to us. Some of our meteors, those of the star-showers, have certainly had that history. What good reason is there for saying that all of them may not have had the like birth-place and life?

The pieces which come into our air in any recurring star-shower belong to a group whose shape is only partly known. It is thin, for we traverse it in a short time. It is not a uniform ring, for it is not annual, except possibly the August sprinkle. How the sun's unequal attraction for the parts of a group acts as a dispersive force to draw it out into a stream, those most beautiful and most fruitful discussions of Signor Schiaparelli have shown. The groups that we meet are certainly in the shape of thin streams.

It has been assumed that the cometic fragments go continuously away from the parent mass, so as to form, in due time, a ring-like stream of varying density, but stretched along the entire elliptic orbit of the comet. The epochs of the Leonid star-showers in November, which have been coming at intervals of thirty-three years since the year 902, have led us to believe that this departure of the fragments from Tempel's comet (1866, I.) and the formation of the ring was a very slow process. The meteors which we met near 1866 were therefore thought to have left the comet many thousands of years ago. The extension of the group was presumed to go on in the future until, perhaps tens of thousands of years hence, the earth was to meet the stream every year. Whatever may be the case with Tempel's comet and its meteors, this slow development is not found to be true for the fragments of Biela's comet. It is quite certain that the meteors of the splendid displays of 1872 and 1885 left the immediate vicinity of that comet later than 1840, although at the time of those showers they had become separated two hundred millions of miles from the computed place of the comet. The process, then, has been an exceedingly rapid one, requiring, if continued at the same rate, only a small part of a millennium for the completion of an entire ring, if a ring is to be a future form of the group.

It may be thought reasonable in view of this fact about Biela's comet, established by the star-showers of 1872 and 1885, to revise our conception of the process of di integration of Tempel's comet also. The more brilliant of the star showers from this comet have always occurred very near the end of the thirty-three year period. Instead of there being a slow process which is ultimately to produce a ring along the orbit of the comet, it certainly seems more reasonable to suppose that the compact lines of meteors which we met in 1866, 1867, and 1868 left the comet at a recent date. A thousand years ago this shower occurred in the middle of October. By the precession of the equinoxes and the action of the planets, the shower has moved to the middle of November. One half of this motion is due to the precession, the other half to the perturbing action of the planets. Did the planets act upon the comet before the meteoroids left it, or upon the meteoroid stream? Until one has reduced the forces to numerical values, he may not give to this question a positive answer. But I strongly suspect that computations of the forces will show that the perturbations of Jupiter and Saturn upon that group of meteoroids hundreds of millions of miles in length,—perturbations strong enough to change the node of the orbit 15° along the ecliptic,—would not leave the group such a compact train as we found it in 1866. If this result is at all possible, it is because the total action is scattered over so many centuries. But it seems more probable that the fragments are parting more rapidly from the comet than we have assumed, and that, long before the complete ring is formed, the groups become so scattered that we do not recognise them, or else are turned away so as not to cross the earth's orbit.

Comets, by their strange behaviour and wondrous trains, have given to timid and superstitious men more apprehensions than have any other heavenly bodies. They have been the occasion of an immense amount of vague, and wild, and valueless speculation by men who knew a very little science. They have furnished a hundred as yet unanswered problems which have puzzled the wisest. A world without water, with a strange and variable envelope which takes the place of an atmosphere, a world that travels repeatedly out into the cold and back to the sun, and slowly goes to pieces in the repeated process, has conditions so strange to our experience, and so impossible to reproduce by experiment, that our physics cannot as yet explain it. But we may confidently look forward to the answer of many of these problems in the future. Of those strange bodies, the comets, we shall have far greater means of study than of any other bodies in the heavens. The comets alone give us specimens to handle and analyse. Comets may be studied, like the planets, by the use of the telescope, the polariscope, and the spectroscope. The utmost refinements of physical astronomy may be applied to both. But the cometary worlds will be also compelled, through these meteorite fragments,—with their included gases and peculiar minerals,—to give up some additional secrets of their own life, and of the physics of space, to the blowpipe, the microscope, the test-tube, and the crucible.

THE BRITISH ASSOCIATION

SECTION D—BIOLOGY

Initiation of a Discussion upon the Value of the "Type-system" in the Teaching of Botany, by Prof. Bayley Balfour.—The speaker remarked that within the last fifteen years there had been a complete revolution in the method of teaching botany and zoology. The old method was practical teaching based on classification. In fact, in the olden times it was taught by means of object-lessons, which were sporadically chosen. In that method the real significance of plant life was completely overlooked, and also the position of the plants in Nature and their relationship to the animal kingdom. The result was that they had naturalists bred who had a wide range of knowledge of plant forms, and able to recognise and name a great number of plants, but of the life-history and sequence of events they were in the dark. The knowledge was a wide but superficial one. The new system was the natural outcome of the progress of the science, and as more knowledge of the minuter forms were obtained, it became necessary to select individual forms to be made types for special study. Thus by degrees a system of teaching was introduced which consisted in the selection of a few characteristic forms, and those were thoroughly studied in their structural and physiological relationship. Thus accurate knowledge of a few types was obtained, and the work now, instead of being in the field, was transferred to the laboratory. That new method was greatly used at the present time, and promised to be more widely introduced by the publication of new text-books running along the lines of that teaching. The old system he did not think produced good results, but he thought that teaching from types, combined with a certain amount of old teaching, would be effective.

In the discussion which followed, Prof. Bower said that in the elementary schools it would be well to give first the classification of the higher plants, and then, if the students succeeded in that part, they might pass to the more strict laboratory learning.—Prof. Hartog condemned the use of the type-system with children under sixteen, and, referring to the college instruction, lamented that the study of botany should have to be regulated by the requirements of the medical students.—Dr. Trimen thought the type-system was apt to give the students a false impression of the vegetable kingdom. They were apt to think that those types covered the whole matter to be studied. It would be well if the system could be extended. As to the question of medical students, they certainly did not require a complete course of technical botany. The teaching of botany in some of the London schools was a mere farce.—Prof. Marshall Ward remarked that the type-system has done good service to education, and pointed out how necessary it is to obtain exact knowledge from the study of actual objects, and how valuable is the training due to their careful investigation. The types should be real, and not imaginary or badly-selected ones.—Dr. Shaw observed that it would be a great mistake to drop biology out of the curriculum of the medical student.—Prof. Hillhouse pointed out that the type-system gave the student the advantage of commencing with simplicity and working up to complexity. The system, to be successful, must be carefully arranged and the selection of types judicious.

Remarks on "Physiological Selection, an Additional Suggestion on the Origin of Species," by G. J. Romanes, F.R.S., by Henry Seebohm.—This was a criticism of the above paper, and was followed by a short discussion, the general conclusion arrived at being to the effect that the paper referred to does not contribute anything essentially new to the theory of Charles Darwin. In criticising this theory, Mr. Seebohm pointed out that its author not only demanded an impossible number of coincidences, but coincidences of such a character that, once granted, the additional coincidence of fertility *inter se* but sterility outside the family was almost, if not quite, an unnecessary incumbrance to it.

On the Morphology of the Mammalian Coracoid, by Prof. G. B. Howes.—The author seeks to show that the importance of a third centre of ossification of the mammalian coracoid has escaped attention; he claims that it is the representative of the true coracoid bar of the lower vertebrata, the coracoid process being held to answer to the epicoracoid plate of the monotreme. He further upholds the view that the mammalian shoulder-girdle has been derived from a primarily expanded sheet-like form.

Some Experiments upon the Acquisition of an Unpleasant Taste as a Means of Protecting Insects from their Enemies, by E. B. Poulton.—This paper dealt with experiments upon the acquisition of an unpleasant taste as a means of protecting insects from their enemies. The author remarked that Darwin thinking of the use of colour in animals, and deciding that it was of use in courtship, came across the bright colours of caterpillars, which were sexless. He directed Wallace's attention to the subject, and he ventured a prediction that the bright colours would be associated with an unpleasant taste or smell, so that lizards, &c., refused to eat them. Experiments proved that this was correct, but, on thinking the subject over, it seemed to the writer that some limitations were required. If an insect was distasteful to a lizard, the former would either be starved or would have to put up with an unpleasant taste. It might probably acquire a relish for what hitherto was disagreeable, and then the distasteful organisms being brilliant and conspicuous would be easily caught and exterminated. Mr. Poulton therefore determined to experiment upon them, believing that it would be found that protection by a disagreeable taste was not so complete as was supposed. He obtained lizards from Italy, but found that that was the case. They often refused an insect at first, and took it afterwards unless they were fed on other things which they liked better. It was found that the small lizards refused a large moth, such as the privet hawk, although entirely harmless and undoubtedly palatable. The larger lizards disposed of it at once, and the former were evidently afraid of it, from its size bearing some comparison to their own. Further, the brilliant black and red moth, the cinnabar, was eaten by the tree-frog, and a second specimen was eaten directly afterwards. It was quite clear that the frog did not dislike the taste, but the moths disagreed with the frog, and they were afterwards found floating in the aquarium. The moth of the buff tip, which was protected by resembling a piece of broken rotten wood, was evidently disliked by the lizards, although they ate it in the end. In some cases disagreeable insects were eaten with a relish by those particular animals, such as the larvæ of the common Crœsus found on birch. The protection was therefore less perfect than was supposed to be the case.

On the Germination of the Spores of "Phytophthora infestans," by Prof. Marshall Ward.—One of the objects of this communication was to bring before the meeting copies of some careful drawings of all the stages of germination. These were obtained by actually watching the development, escape, and germination of the zoospores from the "conidia," following all the phases in *one* individual. The curious effects of light and of abnormal conditions upon the development of the zoospores were also pointed out, and the author showed diagrams of other forms of germination obtained by interfering with the conditions. In the short discussion which followed Prof. Marshall Ward referred to some points in the development and escape of the zoospores of the Saprolegnia.

On the Flora of Ceylon, especially as affected by Climate, by Henry Trimen, M.B., F.L.S.—Attention was first called to the fact that the Island of Ceylon was practically known to Europeans only by its south-west part, being about one-fifth of the whole area, but including the chief European centres, the planting districts of the hills, and the railway system. The remainder of the country is thickly covered with jungle, thinly inhabited, and rarely visited by Europeans, save Government officials and sportsmen. This difference was shown to be due to climate, especially to rainfall. The distribution of the rain, so far as is shown by annual amount, was exhibited by a map, in which the great advantage to the south-west of the lofty forest-clad escarpment of the central mountain-mass of over 7000 feet was exhibited. The south-west monsoon wind commencing at the end of May deposits an immense quantity of rain here, especially in the neighbourhood of Adam's Peak. In the rest of the island this wind becomes dry, and the country is parched and arid until the arrival of the north-east monsoon, which commences in October. This wind brings rain to the whole island, and is the only rain which the dry districts get; in many places it all falls in a few weeks, when the country is completely under water, though parched with drought for the rest of the year. This is very different to the well-known south-west of Ceylon, where, save in February or March, a fortnight's drought is a very rare event. In some parts over 200 inches falls in the year. In these respects Ceylon is an epitome or continuation of the Southern Indian peninsula. The peculiarities of the flora were then gone through in some detail, taking first the low country of the wet districts up to 3000 feet—in which the number of introduced tropical plants was commented upon; then of the lower hills, the principal home of the planting enterprise and tea and coffee estates; and next of the higher or true mountain districts above 5000 feet. In the low country the forest has been much destroyed by the indolent and improvident native mode of cultivation called "chena," and but little virgin forest remains in this portion of Ceylon. From 3000 to 5000 feet the agent of destruction has been European planting, and the forest has almost wholly disappeared. Above 5000 feet, land is no longer sold by Government. Attention was specially called to the concentration of endemic species in this wet district—over 800, or nearly 30 per cent. of the whole flora—and to the strongly Malayan, as distinguished from Peninsular Indian, type of these and of the whole flora. There are no Alpine plants in the Ceylon hills; dense forest covers their summits, but a number of temperate genera are represented. This flora is entirely Indian in type, with no *genus* represented which is not also found in the Nilghiris, but the number of endemic *species* is very remarkable, only about 200 being common to both mountain-ranges. A few remarks were then made upon the naturally open grass lands, called "patanas," in the hills, and their peculiar vegetation. The flora of the great dry tracts of Ceylon was then considered. It is completely distinct from that already considered, being mainly the same as that of the Carnatic or Coromandel coast of India, with no Malayan admixture, and very few endemic species. The whole country is covered with forest, apparently primæval; but in reality much of it is secondary, and not more than 800 or 1000 years old, as is reported by native tradition, and evidenced by the vast remains of temples, tanks, and ancient buildings now overgrown with trees. Most of the timbers of importance in trade are obtained in these districts, and, owing to a very faulty forest conservancy,

there is now but little first-class timber remaining, save in very remote places. The botanical characters of this forest, which is everywhere evergreen, were given; and the paper concluded with a few remarks on the coast flora, which is very uniform throughout the tropical belt of the world.

On "Humboldtia laurifolia" as a Myrmecophilous Plant, by Prof. Bower.—It had been found that there were considerable numbers of plants in tropical countries which were pre-eminently associated with ants. The Italian botanist Picari propounded a general view with regard to the subject that the association was mutually advantageous to the ants and to the plants. He found that the plants gave shelter to the ants, and in certain cases supplied them with food. No one would deny the statement that the relation was advantageous to the ants themselves, but the converse case was not so clear. In some cases it had been found that the ants served to protect the plants, and drove off other insects. Picari also pointed out that in certain cases the plants derived nutriment from the excreta of the ants, but whether that was the case was a view open to considerable discussion. He (Prof. Bower) had come to the conclusion that the ants derived all the benefit, and that there was no advantage to the plants. Not only were the ants provided with a capital lodging, but it might be fairly assumed that from the glands of the plants the insects derived food as well.

On the Artificial Production of a Gilded Appearance in Chrysalises, by E. B. Poulton.—The author remarked that some years ago Mr. T. W. Wood brought before the notice of the Entomological Society of London some proofs that certain chrysalises imitated the colour of the surfaces upon which they threw off their caterpillar skin. The intimation was received with some amount of credulity by leading entomologists, but evidently without sufficient reason. For some years the writer had been working upon the colour of caterpillars in relation to the colour of their surroundings, and he had shown that the colour could be modified in one generation by the alterations of their surroundings. It seemed certain that through some sensory surface, possibly the eye, caterpillars were affected by their external relations, and a corresponding effect was produced in colour. Mr. Wood's experiment was but a special case of some general method of production. He explained the results by supposing that the moist surface of a fresh chrysalis was photographically sensitive to the colour of surrounding surfaces. That appeared to be merely a metaphor, and was unsupported by proof. It was more probable that the colour was produced by the effect upon the caterpillar before it turned to the chrysalis. Experiments were therefore made by the writer to put the fact itself beyond dispute. That was done first by the use of caterpillars of the peacock butterfly and the common tortoiseshell butterfly. It was found that by allowing them to turn to chrysalises upon a white or a black screen very different results were produced. Those upon white paper were often brilliantly golden, although the chrysalises of the tortoiseshell were not quite so golden. Gilded specimens were sometimes found, but their appearances seemed to be produced as a disease. While that was the case of chrysalises found in the fields, the specimens experimented with by the writer were perfectly healthy, and produced healthy butterflies. He then saw that, although a white paper produced a golden appearance, a gilded surface would produce the same effect to a greater extent. That bore in a most important manner on the use of the metallic tints of many of the exposed chrysalises of butterflies: which were thus seen to have harmonised with some metallic surroundings. The next point was to ascertain the period during which the caterpillar was sensitive to the colour of the surrounding surfaces, and the nature of the surface which was affected. The former end was achieved by carefully watching the caterpillars between the time at which they ceased feeding and that at which they turned to chrysalises. It was found that they were sensitive for many hours, even more than a day, before the change took place. The other object was attained by placing the larvæ suspended downwards for ten or twelve hours before the change took place in a tube, of which the upper part was golden and the lower black, the two being separated by a perforated disk. The caterpillar's head was turned round so that it could not see through the aperture, and the result showed that the chrysalises were the colour of the chamber in which the head was placed. Hence it seemed that the sensory surface must have existed upon that area. The full results, however, had not yet been obtained.

The Nervous System of Sponges, by Dr. R. von Lendenfeld.—The author gives an account of his discoveries on this subject up to date. Sensitive and ganglia cells have been observed by him in a good number of sponges. Their locality varies, their shape is constant. They are mesodermal, and appear to preside over the movements of the membranes and pore-sieves, and so regulate the water current. The great difference between sponges and higher cœlenterates is, that in the former the most important organs are mesodermal, whilst in the latter they are ecto- or ento-dermal. He divides the type Cœlenterata accordingly into *Cœlenterata Mesodermalia*, or sponges, and *Cœlenterata Epithelaria* or Cnidaria, as Lulitypes.

The Function of Nettle-Cells, by Dr. R. von Lendenfeld.—The author gives a detailed account of the structure of the nettle-cells, or cnidoblasts, and discusses some biological facts regarding their function. He comes to the conclusion that the nettle-cells are exploded by direct reflex action when the cnidocil is touched, but that the animal can counteract this reflex action by a centrifugally acting nervous irritation in a similar manner as reflex actions are controlled by higher nervous centres in man.

Note on the Floral Symmetry of the Genus Cypripedium, by Dr. Maxwell T. Masters, F.R.S.—In this note the author adverts to so much of the normal structure of Orchids in general, and of Cypripedium in particular, as is necessary for the elucidation of his subject, and proceeds to describe a case of regular peloria in *Cypripedium caudatum*, which shows a reversion to the typical form of Orchids, and goes to prove that the so-called genus Uropedium is only a pelorian form of Cypripedium. The construction of the andrœcium in these plants is then alluded to, and illustrations given of all intermediate stages from monandry to hexandry. The frequently observed tendencies to a dimerous condition, and to the development of the inner row of stamens, are alluded to, and the significance of these changes pointed out. The morphological changes consequent upon hybridisation, and the inferences to be derived from them, are passed under review. The paper concludes with a general summary of the teratological changes observed in the tribe Cypripedieæ.

Notes on Australian Cœlenterates, by Dr. von Lendenfeld.—The author describes the extraordinary mode of development of *Phyllorhiza punctata*, a rhizostomous Medusa discovered by him in Port Jackson. The Ephyra has eight, the next stage twenty-four, the next sixteen, and the adult again eight marginal bodies. If the umbrella margin is injured and newly formed, marginal bodies appear between *all* the newly-formed flaps. Further, the migrations of *Crambessa masaica* at the breeding time are described. This and other species of that genus of rhizostomous Medusæ migrate far up the rivers, like the salmon, to deposit their young. A remarkable change in the colour of *C. masaica*, which has taken place in Port Jackson since the observations of Huxley about fifty years ago, is described. A new variety, which is brown, seems to have been produced or to have immigrated and superseded the *blue* form, which was observed by Huxley and others in that locality. In Port Phlilip the blue variety is still found. The author has found in examining the lower freshwater animals that the freshwater Hydroids and Sponges, as also the freshwater Rhizopoda of Australia, are very similar to the European, whilst the *marine* species of these groups differ very much in the two localities. He concludes that these freshwater forms are very old and conservative, and may be supposed to be the unchanged offspring of old ancestral forms, as such possessing particular systematic importance.

Bugio; the Biological Relations of an Atlantic Rock, by Michael C. Grabham, M.D., F.G.S., F.R.C.P.—Region almost unknown, but interesting as being typical of flora distribution, and of variation in isolation. Author proposed to illustrate present knowledge by reference to prominent forms, animal and vegetable, existing at Bugio, the most unknown of the Dezerta islets.

Dezerta.—Physical characters: Foundation on a narrow ledge; dimensions never much greater; no evidence of ancient contact; not survivals of an ancient continent, but islands in a Miocene sea, deriving their first colonists from Miocene Europe.

Description of Bugio.—Difficulty of access; central volcanic dyke; large proportion of tufas; no sections of old river-beds or surface obliterations; summit showed deep clay-beds and surface deposits of calcareous sand and earth.

Flora.—How related to Madeira; arbitrary distribution; absence of ea-ily wafted forms; *Senecio incrassatus*, Madeiran and Canarian varieties; *Echium fastuosum*, maritime form of; hybrid with *E. simplex*, remarkable perpetuation of perennial growth, and other changes; several instances of fitful distribution; *Chrysanthemum dæmatomma*, a distinct and only species; remarks on cognate Madeira forms; *Monizia edulis*, Dezertan, Salvagic, and Madeiran examples; Miocene origin of.

Fauna.—Rabbit, identical with that of Porto Santo, described by Darwin as having acquired specific characters in shortened length, and colour of skin. *Sea-birds* breeding at Bugio: *Sternus hirundo, Thalassidroma bulwerii*, and many others. *Procellaria anglorum* dominant to the exclusion of *P. major* and *P. obscura*. Influence of birds in migration of plants and mollusks. *Testacea:* Distribution and affinities—*Helix crystallina*, affinities of; *H. erubescens*, distribution of; *H. punctulata*, modification of; *H. Leonina*, area of, and relations; *H. vulgata*, dwarfed example of; *H. polymorpha*, distinct races of; connections of *H. tiarella, H. coronula*, and *H. grabhami*. *Coleopterous Deuca'ion*, isolated species, now related to a Salvagic form.

Summary.—Showing the difficulties attending the determination of the origin and migration of species to be equally great in the component rocks of a group of islands as in the archipelago itself. Agency of man, chiefly in extinction and destruction, illustrated by introduction of opposing or contaminating forms; ravages of Eupatoria and *Phylloxera vastatrix* in Madeira; surviving vigour of Miocene plants. Author's paper only meant to be indicative of those branches and details which might singly occupy the attention of the Section.

The Multiplication and Vitality of certain Micro-organisms, Pathogenic and otherwise, by Percy F. Frankland, Ph.D., B.Sc., F.C.S., F.T.C., Assoc.Roy.Sch.Mines.—In this paper the author records a number of experiments which he has carried out on the multiplication of the micro-organisms present in natural waters, and also on the vitality of certain pathogenic organisms when purposely introduced into similar media. These phenomena have been studied by aid of the method of gelatine-plate cultivation, originally devised by Koch. The first part of the paper treats of the influence of storage in sterilised vessels, upon the number of micro-organisms present in the unfiltered water of the Rivers Thames and Lea, in the waters of these rivers after sand filtration by the companies supplying the metropolis, and in deep-well water obtained from the chalk. Of these three different kinds of water, at the time of collection the unfiltered river-waters are the richest in micro-organisms, containing, as they do, several thousand microbes, capable of being revealed by plate-cultivation, in 1 cubic centimetre of water, whilst the filtered river-waters have this number generally reduced by about 95 per cent., and the number present in the deep-well water rarely exceeds ten per cubic centimetre. On storage in sterilised vessels at 20° C., however, a great change in the relationship of these numbers soon takes place, for whilst the number of organisms in the crude river-water undergoes but little change, or even suffers diminution, that in the filtered river-water exhibits very rapid multiplication, and this increase is even still more marked in the case of the deep-well water. The author suggests that the differences in the rate of multiplication exhibited by these three kinds of water is dependent upon the number of different varieties of micro-organisms which they contain. Thus in the unfiltered river-waters the organisms belong to a number of different kinds; the filtered river-waters exhibit fewer varieties; whilst in the deep-well water the number of varieties is still more limited, the gelatine-plates having generally the appearance of almost pure cultivations. The microbes in the deep-well water will thus be less hampered in their multiplication by hostile competitors than those in the filtered river-waters, and these again less than those in the crude river-waters, in which an equilibrium must have already been established between the various competitors. When the waters were exposed to a temperature of 35° C., the multiplication was in all cases very much more rapid, but both at 20° C., as well as at 35° C., the multiplication was, on prolonged storage, followed by reduction. The pathogenic forms which have been studied by the author are: (1) Koch's "*Comma*" *spirillum* of Asiatic cholera, (2) Finkler-Prior's "*Comma*" *spirillum* of European cholera, and (3) the *Bacillus pyocyaneus*, which produces the greenish-blue colouring-matter frequently present in abscesses. The vitality of these organisms has been studied by introducing minute quantities of their cultivations into sterilised distilled water, deep-well water, filtered Thames water, and London sewage. In these media they present some very striking differences. Thus the *Bacillus pyocyaneus* was found to flourish in all; even in distilled water it was present in largely multipled numbers after fifty-three days. Koch's "*Comma*" *spirillum*, on the orher hand, when introduced into deep-well water was no longer demonstrable after the ninth day, whilst in sewage it was still found in enormously multiplied numbers after twenty-nine days. Finkler-Prior's "*Comma*" *spirillum*, although showing such far greater vital activity than Koch's in gelatine cultures, possesses far less vitality than the latter when introduced into water. Thus in the above-mentioned media it was in no case demonstrable after the first day.

SCIENTIFIC SERIALS

American Journal of Science, September.—A post-Tertiary elevation of the Sierra Nevada, shown by the river-beds, by Joseph Le Conte. In further elucidation of his already published speculations regarding an upheaval of the Sierra Nevada towards the close of the Tertiary epoch, the author here brings forward much additional evidence, also correlating this movement with a contemporaneous elevation in other parts of the western half of the continent. He endeavours to show that the upward movement, which seems to have affected all high latitude regions at that time, but which was oscillatory and therefore temporary on the eastern side of North America and in Europe, on the Pacific slope was permanent, and has largely determined the orographic structure of that region.—The strain effect of sudden cooling, as exhibited by glass and by steel (second paper), by C. Barus and V. Strouhal. In their first communication the authors compared the strains experienced by glass and steel on sudden cooling, by aid of the density variations observed when the bodies carrying strain were annealed, *as a whole*. Here they seek to confirm their earlier inference relative to the temper-strain of glass. They also investigated the density-relations of consecutive similar shells of the Prince Rupert drop, and the optical character of the successive cores. In general it is shown that the optical effect of the temper-strain in glass may be regarded as the analogue of the electrical effect of the temper-strain in steel. In a further communication a more specific inquiry will be made into the causes of hardness itself, with a view to throwing some light on the mysterious transformations of carbon.—Devonian Lamellibranchiata and species-making, by Henry S. Williams. In connection with the publication of Prof. James Hall's monograph on Devonian Lamellibranchs, completing vol. v. part 1 of the "Palæontology of New York," it is pointed out that fossil species, and even genera, are unduly multiplied on totally inadequate data. Species and genera cannot be regarded as established so long as the author himself is unable to distribute the typical specimens, twice alike, without reference to the original labels.—Note on the composition of certain "Pliocene sandstones" from Montana and Idaho, by George P. Merrill. While lately classifying the rocks collected in Montana and Idaho by Dr. A. C. Peale in 1871, the author's attention was called to some fragments labelled as "Pliocene" sandstones. A glance, however, showed that they strongly resembled compacted volcanic dust and sand, and a microscopic examination made it evident that the stones consisted very largely of minute flakes of pumiceous glass sufficiently compacted to be readily broken out into hard specimens, but extremely friable. The specimens are fully described and some speculations offered as to their probable origin. It is added that in Kansas and Nebraska these dusts are collected and sold as "diamond polishing powder," or used in the preparation of the so-called "geyserite" scouring-soap.—Contributions to mineralogy, by W. Earl Hidden, with crystallographic notes by A. Des Cloizeaux. The paper deals with the ipodumene, black tourmaline, xenotime, and twin crystals of monazite from North Carolina; a remarkable crystal of herderite found in 1884 near Stoneham, Maine; a twin crystal of molybdenite from Renfrew, Canada; and the phenacite from Florissant, El Paso County, Colorado.—Turquois from New Mexico, by F. W. Clarke and J. S. Diller. A full analysis and microscopic study is given of some specimens from the turquois mines of Los Cerillos, New Mexico, about 22 miles south-west of Santa Fé. The turquois-bearing rock appears to be eruptive, and probably of Tertiary age, while the small size of the veins and their limited distribution show that the turquois is of local origin, possibly the result of alteration of some other mineral.—On the electrical resistance of soft carbon under pressure, by T. C. Mendenhall. In reply to Prof. Sylvanus P. Thompson's objections, the author describes some fresh experiments fully confirming his views regarding the change in the resistance of carbon due to change of pressure. In the form of compressed lampblack the electrical resistance of carbon varies greatly with the pressure to which it is subjected, and the variation is mainly due to a real change in the resistance of the carbon itself.—Com-

parison of maps of the ultra-violet spectrum, by Edward C. Pickering. Prof. Rowland's recently published photograph of the solar spectrum is compared with Draper's map of the ultra-violet portion of the spectrum prepared in 1873, with which it is shown to agree very closely. The mean difference for the seventy-six lines compared was 0·012, corresponding to about 1/800 inch upon the Draper map. It may therefore be assumed that the probable error of a wave-length derived from this map will not exceed 1/100 unit if the correction here given be first applied.—On two hitherto undescribed meteoric stones, by Edward S. Dana and Samuel L. Penfield. One of these meteorites was found, in 1869, between Salt Lake City and Echo, Utah; the other, in 1846, near Cape Girardeau, South-West Missouri. Olivine is the most prominent constituent of the former, while the latter is a light gray chondrite.

SOCIETIES AND ACADEMIES

PARIS

Academy of Sciences, September 20.—M. Fizeau in the chair.—Kinematic analysis of human motion, by M. Marey. In the figure accompanying this paper are represented the successive attitudes of the lower right limb while describing a complete step. This action is shown to be divided into two periods, a rest and a rise, which are again subdivided into four unequal phases, of which the last three belong to the period of rise. The simultaneous movements of ankle, knee, and hip are explained, and it is pointed out that, whatever be the velocity of the pace, the form of the various trajectories here described is maintained in their salient features. But, the more rapid the motion, the more is the tendency of the centre of gravity to approach a straight line parallel with the surface of the ground. —"Modern Kinetics and the Dynamism of the Future," by M. G. A. Hirn. This is the title of a new work, which the author presents to the Academy with some remarks explaining its general purpose. After replying to the various objections raised against his general principles, he deals with the arguments which, as he maintains, render henceforth indefensible the kinetic theory of the gases, referring to molecular movements most of the properties of these bodies. Three arguments are advanced of such a nature that he believes future physicists will wonder how this kinetic theory could ever have been accepted for a single moment. Even were it correct, it would not follow that light, radiant heat, electricity, magnetic attraction and repulsion, and gravitation were due to movements of ponderable matter, far less that thought itself was nothing more than a molecular movement. But the reverse is not true, so that with the collapse of the kinetic theory of the gases fall the kinetic theories in general, which claim to explain all possible phenomena of the universe by invisible movements of matter. The doctrine here substituted for kinetic force, he thinks, explains quite as easily, and much more rationally, the universal phenomena of the physical world. He does not, however, hope at once to convince all minds of what they should have long ago been themselves convinced. Interpretations formulated *a priori*, and apart from experience and observation, have unfortunately more vitality than truths gained to science by the patient study of Nature.—Observations of Winnecke's comet made at the Observatory of Nice (Gautier equatorial), by MM. Perrotin and Charlois. The results of these observations, which extend over the four days from August 27 to September 1, are embodied in tables showing the positions of the stars 25339 Lalande, 25588 Lalande, 4989 Schjellerup, 5004 Schjellerup, and the apparent positions of the comet.—On the transformation of algebraic surfaces in themselves, by M. Emile Picard. A proposition analogous to that of Schwarz is thus formulated: Algebraic surfaces capable of being transformed in themselves by a bi-rational substitution, including two arbitrary parameters, are of the genus zero, or one.—On a class of differential non-linear equations, by M. Roger Liouville.—Historical note on a series whose general term is of the form $A_n (x - a_1)(x - a_2) \ldots (x - a_n)$, by M. G. Eneström.—Researches on the structure of the nerve-centres in the Arachnidæ, by M. G. Saint-Remy. Having in a previous communication dealt with the structure of the brain of the scorpion, the author here extends his observations to the spider family, and more particularly to *Tegenaria domestica*, *Epeira diadema*, and *Phalangium opilio*. In these groups he shows that the brain offers the same plan of organisation as that of the Scorpionidæ.—Fresh researches on the configuration and extent of the Carmaux Coal-measures, by MM. Alfred Caraven-Cachin and Grand. In this basin, which extends for nearly six miles from Rozières to Saint-Quentin, there are in some districts three successive coal-deposits with a joint thickness of over 31 metres underlying Tertiary formations 156 metres thick. They appear to have been deposited horizontally, always in shallow water, the land subsiding sometimes slowly, sometimes intermittently, during the whole period of their formation.—Note on the affinities of the Oolitic floras in the West of France and in England, by M. L. Crié. In this paper the author communicates the first results of his studies of the Oolitic floras of these regions. The conifers are represented at Mamers (Sarthe) and at Scarborough (Yorkshire) by traces of Brachyphyllum, which present a remarkable identity. Certain imprints at Scarborough also show a strong resemblance, in the disposition of the foliage, and especially in the veinous system, to *Otozamites marginatus*, Sap., which is so characteristic of the Mamers flora. About the middle of the Oolitic period this group must have covered certain upheaved tracts in the Venetian Alps, in the neighbourhood of Mamers, and at Scarborough.—The waterspout of September 14 at Marseilles, by M. Barthelet.

BOOKS AND PAMPHLETS RECEIVED

"How Readest Thou? or the First Two Chapters of Genesis," by E. Dingle (Partridge and Co.).—"The Chalk and Flint Formation," by W. B Galloway (Low and Co).—"Life-History of Plants," by Prof. D. M'Alpine (Sonnenschein)—"Tobacco: a Farmer's Plant," by P. M. Taylor (Stanford).—"Therapeutics founded upon Organopathy and Antipraxy," by W. Sharp, M.D. (Bell and Sons).—"Report of the Iowa Weather Service, January to April 1883," by Dr. G. Hinrichs.—"Scientific Romances: No. v. Casting out the Self," by C. H. Hinton (Sonnenschein).—"Lessons in Elementary Dynamics," by H. G. Madan (Chambers).—"Studies in Ancient History," N.E., by J. F. McLellan (Macmillan).—"Manual of the New Zealand Coleoptera," parts 3 and 4, by Capt. T. Brown (Didsbury, Wellington).—"School of Forest Engineers in Spain," by Dr. J. C. Brown (Oliver and Boyd).—"Hand-book of Mineralogy," by J. C. Foyr (Van Nostrand, N.Y.).—"Monographs U.S. Survey," vol. ix. (Washington).—"Hommage à M. Chevreul, à l'Occasion de son Centenaire" (Alcan, Paris).—"The Handy Natural History," by J. G. Wood (Religious Tract Society)—"General Report on the Operations of the Survey of India Department," 1884-85, by Col. G. De Prée (Calcutta).—"Notes on the Bones of a Species of Sphenodon," by W. Colenso.—"The Economical Aspects of Agricultural Chemistry," by H. W. Wiley (Wilson, Camb., Mass.)—"Report on the Decapod Crustacea of the *Albatross* Dredgings off the Coast of the United States," by S. I. Smith (Washington).—"Metodo per Misurare la Dilatazione Termica dei Corpi Solidi: Memoria di F. Artimini (Firenze).—"The Cause of Electricity, with Remarks on Chemical Equivalents," by G. T. Carruthers (Benares).

ORCHIDS

Reichenbachia: Orchids Illustrated and Described. By F. Sander, assisted by Eminent Scientific Authorities. Magnificently Illustrated in Colours. (London: Sotheran and Co, 1886.)

THE first two parts of a new illustrated work on orchids are now before us. It is called "Reichenbachia," in honour of Prof. Reichenbach, of Hamburg, our greatest living authority on the Orchideæ. The author of the work, which is to be published in monthly parts in an "ordinary," and an "imperial" edition limited to one hundred copies, is Mr. F. Sander, a well-known importer of, and dealer in, orchids at St. Alban's. While justice should be done to the author's energy and enterprise in undertaking so sumptuous and, so far as it has gone, so promising a production, it should be remembered that his business interests are connected with it.

Each part of the larger edition contains four plates in imperial folio, with botanical and horticultural descriptions in English, French, and German, geographical and cultural details being also given. The botanical descriptions are by Prof. Reichenbach, who is responsible also for the dissections. Why, we may ask, are the descriptions of the dissections sometimes in English and sometimes in Latin? This query leads to the remark that the custom of giving botanical descriptions in Latin has led to the creation of what we venture to designate as a most extraordinary, barbarous, and unintelligible jargon. In this work, as in any other botanical book where the descriptions are in Latin, words are to be found in numbers which are in no sense Latin. Scientific descriptions may require the invention of words or terms; but the supposed convenience of their being understood, when in Latin, by men of science of all nations is hardly a sufficient justification for the wholesale creation of such a language. We may add that we submitted one of the Latin descriptions in this work to the head master of a great school, who was unable even to suggest a meaning for some of the terms.

The plates in "Reichenbachia" are unquestionably superior, taking them one with another, to those in any modern botanical work we are acquainted with. They are far in advance both in drawing, and in truth and delicacy of colouring, to the "Orchid Album" of Messrs. B. S. Williams and Sons, or the "Lindenia" of the Continental Horticultural Company of Ghent. They do great credit to Mr. H. G. Moore, one of the best of our young horticultural artists, and to Mr. J. L. Macfarlane, whose work as a natural history lithographer it would be difficult to surpass. We are disposed to take exception to a remark made by Prof. Reichenbach, under Tab. I., *Odontoglossum crispum*, that Bateman's "Monograph of Odontoglossum" is "perhaps the finest book on orchids that has ever been issued." In our judgment it will not compare with the earlier work by the same author, the splendid "Orchidaceæ of Mexico and Guatemala." Of the eight plates in the two parts under review we consider Tab. IV., "*Odontoglossum Rossii rubescens*," the truest to nature, as well as the most artistic. The least satisfactory is Tab. VI., *Calogyne cristata maxima*," in which the hairs on the tip, though shown in the dissection, are not even suggested. We must here, with all respect and deference to Prof. Reichenbach, demur to the varietal name *maxima*. The flowers of this variety may be a little larger than the type, but if it be named *maxima*, what are we to call a larger variety, should one turn up, as is by no means unlikely? These superlatives are more in keeping with the aims and objects of trade than with those of scientific nomenclature. The nurseryman naturally revels in such adjectives as "superbissima," "brilliantissima" (!), "delicatissima," "magnifica," &c., but science should repudiate them. Tab. III. represents a recently introduced Venus's Slipper, from the Malayan Archipelago, called *C. Sanderianum*, which has not been seen in flower, we believe, outside Mr. Sander's nursery. We hope the remarkable drawing does not do more than justice to it. The plant is especially interesting in that it is an almost exact Eastern counterpart of the now well-known *Cypripedium caudatum* from South America, which was first flowered by the late Mrs. Lawrence, of Ealing Park, about fifty years ago. Tab. I. represents the most beautiful and popular, and what is now the commonest and cheapest of the Andean cool orchids, *Odontoglossum crispum*. We cannot admit that there is any scientific distinction maintainable between *O. crispum*, *O. Bluntii*, and *O. Alexandræ*, such differences as there are being purely horticultural. In view of the latest achievement of the busy laboratory of Messrs. Veitch and Sons, where during recent years more species of one genus, Cypripedium, have been created than have been gathered for us from nature by the whole army of collectors, botanists will have to reconsider, it would seem, not only the species of orchids, but the genera. Messrs. Veitch have now in flower a hybrid between *Sophronius grandiflora* and *Cattleya intermedia!* At the Conference last year, and again at the recent Provincial Show of the Royal Horticultural Society at Liverpool, the attention of botanists and horticulturists was drawn to the confusion into which the nomenclature of orchids had fallen, a confusion rapidly becoming worse confounded. We have examples of this in *Odontoglossum crispum* with its many synonyms and varieties, and in *Cattleya Dowiana*, Tab. V., which was re-christened *C. aurea*, simply because it was found in a new habitat. A new name should never be accepted, any more than a new genus or species, unless it be stamped with the approval of a recognised botanical authority. At present the latest and rawest recruit among the rapidly increasing band of orchid growers thinks nothing of coining a new specific or varietal name, which generally takes the shape of a supposed Latinisation of his own name.

The cultural directions are generally judicious. It is impossible to lay too much stress upon the necessity of giving orchids, whether Mexican or East Indian, the period of rest they have in nature. Mr. Sander proscribes houses with a north aspect for cool orchids. Some of the finest Odontoglossa and cool Oncidia we ever saw were grown in a house facing due north. We cannot indorse the recommendation of cocoa-nut fibre refuse or peat-moss manure either on or under stages. They rapidly decay, and become covered with fungi, and full of wood-lice and

other pests. One of the great difficulties in growing orchids and other plants under artificial conditions is due to the injury caused by insects. Any one with a knowledge of chemistry and of vegetable physiology would find, we believe, a profitable field of inquiry in this direction. Amateurs and the trade alike have dealt with this difficulty by rule of thumb for generations, and confined themselves to smoking plants with tobacco in various shapes, and treating them with quack insecticides. So far as tobacco-smoke is effectual, its effect is probably due to the nicotine it contains. There can be no insuperable difficulty in charging the air of a closed house with nicotine fumes sufficiently to destroy insects, and in thereby getting rid of the pungent and injurious smoke produced by burning coarse tobacco and brown paper. In conclusion we may express a hope that this work will not come to a premature end, like some of its predecessors, but live to fulfil the promise of the parts here noticed.

ARC AND GLOW LAMPS

Arc and Glow Lamps. A Practical Hand-Book on Electric Lighting. By Julius Maier, Ph.D. (London: Whittaker and Co., and G. Bell and Sons, 1886.)

WE should have been glad if it had been possible to speak more favourably of Dr. Maier's work than can be done after a conscientious reading of it; for Dr. Maier has made himself so thoroughly master of our language, and has taken such obvious pains to acquaint himself with the literature of electric lighting, that we cannot help wondering how so able a man has produced such a disappointing treatise. Much of the work appears to have been translated from Merling's and other German books on electric lighting. Perhaps it is to this composite origin that the defects are due which a reviewer is bound to point out.

The first 82 pages are occupied by generalities such as the laws of production of heat in the circuit, the efficiency of dynamos, electric and photometric measurements. Then come 60 pages upon arrangements of leading wires and of lamps in installations for electric light, including the so-called "secondary generators" or induction coils for distributing alternating currents. At p. 140 we at last reach arc lamps, the principal types of which are described with care. Twelve pages are allotted to the now almost obsolete electric "candle," and at p. 263 we enter upon the glow lamps. These are described all too briefly, especially so far as relates to the details of manufacture; but the data as to tests of efficiency and durability of the lamps are most satisfactorily summarised. This chapter includes an abstract of the tests made by the Philadelphia Committee, whose method of testing the lamps and of deducing the "mean spherical intensity" of the illumination is perhaps more scientific than that of any of the numerous Exhibition committees who have reported on electric lamps. The book concludes with special chapters on the application of electric light to lighthouses, ships, mines, railway trains, photography, and operative surgery.

There are several contradictory statements in Dr. Maier's book. On p. 270 he tells us that after the inventions of Greener and Staite in 1846 electric lighting fell completely into oblivion till 1873, when Lodyguine took up the question. Yet on p. 148 we find a description of improvements made in 1857 by Lacassagne and Thiers, and on p. 362 we find that electric light has been used for stage purposes ever since the production of Meyerbeer's opera of "Le Prophète" in 1846. The records of the English Patent Office between 1846 and 1873 show abundant evidence to negative Dr. Maier's statement. In that interval came the invention of the lamps of Serrin, Chapman, Way, and Browning, and the successive improvements of Holmes, Siemens, the Varleys, Wheatstone, Wilde, and Gramme in the magneto- and dynamo-electric generators for lighting purposes. On p. 32 it is stated that the drawback of the system of arranging lamps in series in one circuit lies in the fact that the individual lamps are not independent of one another; yet on p. 94 and p. 184 it appears that there are means by which any lamp is made quite independent of all the other lamps in the series.

We object entirely to Dr. Maier's classification of arc lamps into "monophotal" and "polyphotal"; these high-sounding names being respectively applied by him to lamps that will not work, and those that will work, when more than one is placed in series in the same circuit. The distinction is entirely misleading: for the question whether one or many lamps can be worked together depends quite as much on the dynamo as on the lamps. Every one knows that modern dynamos are so designed as to work under one of two standard conditions: they must either yield a constant current in the line, or else must maintain a constant difference of potential between the distributing mains. As a rule arc lamps arranged to work in series in a constant-current circuit will not work if set in parallel across the mains of a constant-potential network, and *vice versâ*. The true classification of lamps should therefore be into constant-current lamps which will work many in series, and constant-potential lamps which will work many in parallel. Probably the only lamp that will not fall in one of these two categories is the old regulator of Duboscq and Foucault. Most of the lamps classified by Dr. Maier as monophotal, and which according to him can only be worked each with its own separate dynamo, will work perfectly well in parallel with one another on a constant-potential system of mains. One consequence of Dr. Maier's curious classification is that when he comes to the Gülcher lamp, which is an excellent lamp for lighting in parallel, he cannot put it under either head, and it is relegated to miscellaneous lamps. Of the lamps which he describes as polyphotal, the very first is Lontin's modification of the Serrin lamp; but curiously enough the lamp figured and described in the text is *not* Lontin's but is the old unmodified Serrin, which, though stated by Dr. Maier to be monophotal, is really exactly in the same category as Gülcher's lamp. The lamp of Street and Maquaire is stated to be different from all other arc lamps in employing a vibratory principle: the author appears not to know that the lamps of Clark Bowman, Newton, and Pieper also have vibrating mechanism. Amongst other erroneous points it is stated on p. 321 that Edison was the first to point out the advantage of high electromotive force in the glow lamp; on p. 324 that the Lane-Fox pump gives "infinitely better results" than the Sprengel or Geissler pumps; on p. 305

that carbon is deposited "electrolytically" in the flashing process of heating in a hydrocarbon vapour; on p. 31 that it requires "several" dynamos instead of one to yield an electromotive force of 2500 volts; on p. 27 that Ohm's law is true for the whole circuit only, and not for its parts; on p. 91 that a shunt coil was first used in an arc lamp by Von Hefner Alteneck; on p. 14 that "the velocity of a body falling through a vacuum" is "9·81 metres in one second." The definition of the ohm as originally fixed in 1862 by the Committee of the British Association was certainly not "equal to the resistance of a column of mercury of 104 centimetres in length and 1 square millimetre section," as stated on p. 13. There is a grossly misleading extract from Merling's work given in pp. 15 to 28 on the distribution of heat in an electric circuit. The old battery rule of arranging internal resistance equal to the external to get maximum current is trotted out, without a word of warning that this is an arrangement always to be avoided on account of its bad economy; and as if this were not bad enough, an algebraic corollary is added showing that this arrangement of maximum current is such as to make the maximum rate of output of heat in an external conductor of given resistance one-quarter of the output that there would be in the circuit if the battery were short-circuited. The student will at once draw the erroneous conclusion that at least three-quarters of the heat must necessarily always be wasted. But to make matters still worse, on p. 24, where the grouping of the battery is still under discussion, it is stated that in "no case can we obtain more heat," in the conductor of given resistance, than the quarter previously mentioned. This is entirely untrue; for if the cells be grouped all in parallel so as to reduce the internal resistance to a minimum, then a very high percentage of the heat of the current—practically all of it—will be obtained in the conductor of high resistance, and the zincs of the battery will consume more slowly. There are several other matters to which exception must be taken: a crude assertion that a Gramme dynamo is better than a Siemens, which may have been true in 1878; crude statements true perhaps of a particular dynamo or a particular lamp, but not true of dynamos or lamps in general; crude advice to makers to arrange their lamps so as to keep the resistance of the arc constant; crude arguments in favour of using shunt-wound electro-magnets in arc lamps, all reasons being given except the right one. Three times Dr. Werner Siemens's name is erroneously given as Wilhelm Siemens. Lastly, electric engineers will be surprised to find amongst the practical hints nothing about the "striking" of the arc, or about the "hunting" action of lamps and its avoidance. It is to be hoped that these matters will be remedied when the author comes to rewrite his book for a second edition.

S. P. T.

DISORDERS OF DIGESTION

On Disorders of Digestion. By T. Lauder Brunton, M.D., F.R.S. (London: Macmillan and Co., 1886.)

THIS book is a reprint of a series of disconnected papers which the author has contributed during the last thirteen years to various periodicals and Societies, and is prefaced by the Lettsomian Lectures, "On Disorders of Digestion," in which the author has collected together into one homogeneous whole many of the observations and illustrations which he had introduced into his earlier papers. These lectures give a most admirable *résumé* of the latest advances in our knowledge of the complicated processes of digestion and of mal-digestion, and the succeeding papers form a most interesting study of the gradual development of the author's views.

The main idea which runs throughout the whole work, and which the author more than any one else in this country has developed, is that, in mal-digestion, products are formed which in their passage through the liver disorder its functions, and on reaching the general circulation act more or less as poisons, producing languor, listlessness, heaviness of the limbs, great depression of spirits, and headache.

Brieger especially has worked out both chemically and physiologically the products of digestion and decomposition of food-stuffs. He has been able more or less successfully to separate several alkaloids which have most powerful effects when administered to animals. Several resemble very closely in their effects muscarin, the active principle which Prof. Schmiedenberg has separated from several species of mushrooms. This when administered to animals causes vomiting, purging, dyspnœa, and prostration, and it has been found that atropia is an efficient antidote. Many of these alkaloids are detained by the liver, and excreted with the bile into the intestine, again to be later on re-absorbed by the portal circulation, and may thus circulate in the portal system without ever entering the general circulation. Lead, copper, and other minerals, when administered by the mouth, often circulate in this manner, and the same process is offered as an explanation of the trivial effects of curara when swallowed, while its subcutaneous injection is lethal.

The author's views are corroborated by recent researches which allot a most important part in all digestive processes to bacteria and other micro-organisms. Cultivations carried on at Leipzig have shown that twenty-five micro-organisms are commonly found in the mouth, and that these under certain conditions may occasionally develop in various parts of the alimentary canal. Some develop large volumes of gas, and others lactic, caproic, caprylic, butyric acids, or other complex bodies during their growth. It is extremely probable, therefore, that the excessive multiplication of these micro-organisms generates the products of mal-digestion. A healthy condition of the alimentary canal and its secretions is inimical to their growth. A slight degree of acidity—less even than that normally present in gastric juice—is quite sufficient to check their growth.

These experiments open up quite a new field for the treatment of dyspepsia: the actions of old well-established remedies receive a new explanation, and new drugs will be pressed into the service.

Bitters are said to be beneficial because they check the secretion of mucus, which is a suitable nidus for some bacteria; mineral acids, mercury and salicylic acid are more strongly recommended than ever because of their antiseptic properties; charcoal, bismuth, and alkalies base their claim for support on their stimulation of the gastric secretion.

The title of the book is used in a very wide sense, and at the end is a series of articles on renal secretion, its disorders and treatment. Nowhere does the author better show his powers of dealing with complicated problems—marshalling together his facts, and then in the most lucid and pleasant manner, often assisted by apt illustration, setting forth his view of the question. Great stress is laid upon the distinct blood-supplies of the glomeruli, and of the convoluted and straight tubes, and upon the distinct regulating mechanisms, while an attempt is made to classify diuretics accordingly.

ALCHEMY

Die Alchemie in älterer und neuerer Zeit. By Hermann Kopp. Pp. 685. (Heidelberg: Carl Winter, 1886.)

THIS work is in two parts; the first part treats of alchemy up to the year 1775, and the second part subsequent to this date.

It is not written purely for the chemist, and indeed the student who looks here for the minor details of alchemy will be disappointed. These have already received ample treatment at the hands of Prof. Kopp in his "Beiträge zur Geschichte der Chemie," and the object of the present work is rather to lay stress upon the philosophy of the alchemists, to give some account of the organisations from which they received support, and to point out that such organisations had wider aims and a more distinguished following than is perhaps generally known. It will be read with as much pleasure by the student of literature and history as by the chemist. The difficulty of dividing a work of this nature into chapters is no doubt great, but we cannot help thinking that such a division would have been conducive to clearness; there is, however, a table of contents, a full and well-arranged index, and change of subject is indicated in the text by a break in the paragraphing. We have presented to us alchemy as a search after scientific truth under the guidance of principles which if ill-founded were yet sufficiently real to attract philosophers as well as representatives of wealth and power; as a science which survived persecution and failure, and whose allurements outlived the discredit brought upon it by dupes and swindlers. The relation between alchemy and medicine is traced in an interesting and careful manner. Although it has been by no means the author's intention to act as biographer, yet we have, if we may so speak, medallions of many of the more distinguished alchemists, in which the features calculated to indicate the growth and progress of principles are brought out with great clearness. Of such a type is the sketch of Leonhard Thurneysser, whose chequered career is indeed a romance of real life. In the second volume we have an interesting account of the "Rosenkreuzerbund," a secret society founded by Christian Rosenkreuz at the beginning of the fifteenth century. In this and kindred societies the "brothers" were encouraged to travel, gaining experience and knowledge which at their periodical meetings were retailed for the common interest and instruction of the members. Considerable latitude was allowed to the individual, and the following lines, by one who was himself connected with such a society, show that there was not always a servile respect for tradition :—

DER WEISE UND DER ALCHYMIST

Gesund und fröhlich, ohne Geld
Lebt einst ein Weiser in der Welt.
Ein Fremder kam zu ihm und sprach : "Auf meinen Reisen
Hört ich von deiner Redlichkeit ;
Du bist ein Phönix unsrer Zeit.
Nichts fehlt dir als der Stein der Weisen.
Ich bin der Trismegist, vor dem sich die Natur
Stets ohne Schleier zeigt ; ich habe den Merkur,
Dadurch wir schlechtes Blei in feines Gold verkehren—
Und diese Kunst will ich dir lehren."
"O dreimal grösster Trismegist !—
Versetzt der Philosoph—du magst nur weiter reisen !
Der ist ein Weiser nicht, dem Gold so schätzbar ist.
Vergnügt sein ohne Gold, das ist der Stein der Weisen."

The constitution of these societies is explained, and we are initiated into the mysteries of the various grades of rank: the juniors, the theorists, the practitioners, the philosophers, the minors, the majors, the adepts, the magister, and finally that rarest honour, the magus.

A considerable space is occupied with the history of one who was ever active in the welfare of such organisations—Georg Forster—born near Danzig in 1754. He was a remarkable man in every respect, unstable to a degree, holding peculiar opinions on religious topics, unskilled in all which contributes to success in the general occupations of life, and yet wielding powerful influence in the circle within which he moved. His earlier travels led him to England, where he was at the age of thirteen engaged in teaching French and German in a school at Warrington; then he passed into the East India Company's service; whilst at the age of eighteen we find him as a companion of Cook in his second voyage round the world; later he returned to the Continent, and became Professor of Natural History at Halle. Some thirty pages are devoted to a charming sketch of Georg Forster's character, and we do not know any other passage which affords such enjoyable reading.

S. Th. Sömmering was Forster's bosom friend and companion, a man not unlike him, and who shared all his trials and difficulties. In the concluding pages of the book it is shown how with the dawn of dynamical and quantitative ideas in chemistry at the close of last century, alchemy underwent modification, and, ultimately, rapid decline. One is tempted to wish that the author had given a concluding chapter on the rise and development of the principles of chemistry as shown by an examination of the doctrines of the alchemists.

Notes and references have been freely used throughout the work, and where remarks of such a length are required as to interfere with the continuity of the text, these are arranged in an appendix. These addenda occupy over 200 pages, and constitute in fact a most valuable contribution to the history of alchemy. The style and general character of the work will appear from the remarks that have been already made, and if there are occasionally passages that are somewhat abstruse, yet on the whole we have a clearness and picturesque delineation excelling in our opinion, anything that has hitherto appeared on the subject, and we congratulate the veteran author on his success in a new phase of literary effort. Our English readers will be glad to know that the book is printed in Roman type, and can be had bound in boards.

G. H. BAILEY

OUR BOOK SHELF

La Terre des Merveilles. Par Jules Leclercq. (Paris: Librairie Hachette et Cie., 1886.)

IN this volume M. Jules Leclercq describes a visit made by him a few years ago to the Yellowstone National Park, during which he saw all the sights of this *terre des merveilles.* The writer is already well known in his own country as an accomplished writer of popular books of travel, and accordingly he makes the most of the Yellowstone region and its wonders. His sketches of these are preceded by a very interesting chapter on the early explorations of the territory, from the visits of the first adventurous trappers. There are two maps—one a detailed map of the "Park," the other a general map of part of the United States to show the position of the Yellowstone region. There is also a considerable number of illustrations. The volume is published in Hachette's "Collection des Voyages illustrés," and is a clever, well-written popular account of a district full of natural wonders.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

The Cereals of Prehistoric Times

MY friend Mr. Carruthers in the interesting address delivered recently to Section D of the British Association, makes a remark which I confess surprises me. He says (NATURE, September 9, p. 453):—"It is remarkable that in our own country, with all the appliances of scientific cultivation and scientific farming, we have not been able to appreciably surpass the grains which were harvested by our rude ancestors of 2000 years ago." He mentions in support of this conclusion that "the wheat from lake-dwellings in Switzerland for which I am indebted to Mr. J. T. Lee, F.G.S., are fair samples."

This is certainly a striking fact. The persistence of specific and even of varietal types in a country like Egypt is what we might expect, because the very preservation of the material evidence is a proof that the physical conditions have persisted likewise. But that cultivated plants have remained unaltered since the Stone Age seems a conclusion difficult to accept in the face of every-day experience as to what can be done in modifying them. The data collected by Prof. A. De Candolle ("L'Origine des Plantes cultivées," pp. 284, 285) leads me, I think, to the conclusion that Mr. Lee's specimen must be exceptional. Prof. De Candolle mentions three varieties of wheat as cultivated in the Stone Age; of these he says:—"Aucune n'est identique avec les blés cultivés de nos jours. On leur a substitué des formes plus avantageuses." Two of these have been obtained from lacustrine dwellings. He remarks that the most ancient lacustrine people of Western Switzerland cultivated a wheat with small grains, which Heer has carefully described and figured under the name of *Triticum vulgare antiquorum.* These people he regards as contemporaries of the Trojan war, if not older. The culture of this kind of wheat persisted in Switzerland till the Roman conquest. Unger found the same form in a brick of the pyramid of Dahschûr in Egypt of the date B.C. 3359. The other variety (*Triticum vulgare compositum muticum,* Heer) was less common in Switzerland in the first age of stone, but is the one most frequently found in the less ancient lake-dwellings of Western Switzerland and Italy.

W. T. THISELTON DYER

Physiological Selection and the Origin of Species

HAVING written for the *Fortnightly Review* a full reply to Mr. Wallace's article in that journal, I will not here anticipate what I have there to say. But, seeing that he has repeated in these pages the substance of his criticism, I will here also repeat the substance of my reply. On the present occasion, therefore, it is enough to remark that I have never made the "extraordinary statement that, during his whole life, Mr. Darwin was mistaken in supposing his theory to be a theory of the origin of species." On the contrary, as I shall hereafter show, so far as this matter is concerned, both my opinions and my statement of them are in full agreement with those presented in Mr. Darwin's works.

Without wishing to discuss with Mr. Francis Darwin the meaning of the sentence which he quoted from the "Origin of Species," I feel it is only due to my own understanding to give the following explanation. If any one will turn to the sentence in question (p. 247, 6th ed.), he will find that it constitutes an integral part of an argument showing that sterility between species cannot have been brought about by natural selection. The argument is that, *even supposing sterility with parent forms to be an advantage,* it is an advantage which could not be seized upon by natural selection, and hence that some other explanation of such sterility must be found. Now, so far as I can see, there is here not only no shadow of the theory of physiological selection, but the whole argument is proceeding on totally different lines. For the very essence of this theory is that the sterility in question *need not be supposed to be an advantage,* and therefore that any variation in the way of such sterility *does not require* to be selected through the struggle for existence, being of its own nature a variation which survives. In no part of Mr. Darwin's writings can I find even the most distant allusion to the possibility of this particular variation being thus a variation *sui generis*—itself a cause of specific differentiation, and, as such, independent of natural selection. Least of all can I find evidence of any such allusion in the pasage referred to, seeing that the argument here consists in expressly regarding the variation of sterility as resembling variations in general, and therefore in *not* regarding it as possibly presenting the highly peculiar quality of being survivable *per se.* And, considering how fully Mr. Darwin has given his reasons for rejecting many ideas much less feasible, I confess it appears to me a most extraordinary and unaccountable thing that he should nowhere have so much as mentioned this alternative, had it ever been familiar to his mind. I may add that, if any reasonable ground can be shown for supposing this to have been the case, it would cause me to abandon the whole research.

Mr. J. H. A. Jenner's remark cannot apply to the particular kind of variation with which alone my theory is concerned, because, if so, it would amount to saying that the more sterile the variety is with its parent form the more will this sterility be increased by intercrossing with that form, which is absurd. But with regard to many other kinds of *beneficial* variation the remark of course is true.

I am greatly obliged to Mr. Evershed for directing my attention to Mr. Catchpool's letter in NATURE (vol. xxxi. p. 4). Having obtained a copy of the issue referred to, I find, as he says, that "the theory of physiological selection is very clearly put forward." Moreover, the difficulties against the theory of natural selection on account of inutility and sterility are very clearly stated. I may take this opportunity of requesting any of your readers who may know of any previous publications of the theory—no matter how vague or sketchy—to be kind enough to furnish references.

GEORGE J. ROMANES

Geanies, Ross-shire, September 18

Cooke's "Chemical Physics"

IN your issue of September 2 (p. 405) I find under the cover of a review of Cooke's "Chemical Physics" that Prof. Armstrong has been good enough to quote a passage from my "Lessons in Elementary Chemistry," though without naming the source, concerning Avogadro's law, about which he asks the question, "Could anything be more misleading and inaccurate?" My friend appears to be no exception to the well-known rule as to critics failing to read the books they review, for a note on the same page (55) disposes of the "inaccuracy," whilst the "misleading" statement is explained further on (p. 154). On the other hand, Dr. Armstrong has not followed the usual practice of critics, who, not being authors, escape from the danger of a retort courteous from those whom they find fault with; and hence I feel sure he will forgive me in saying that, whilst fully agreeing with him in the statement that a knowledge of mathematics is advisable for a chemist if he is to understand physics and physical

methods, I still am bold enough to ask whether anything can be "more misleading and inaccurate" than the formula for reduction for temperature and pressure given in both editions of his "Organic Chemistry" under the description of Dumas's vapour-density method. And to add that no excuse can here be found of a correction given elsewhere, or of the fact that it may be desirable sometimes to state a case broadly to begin with and to define it more closely afterwards. HENRY E. ROSCOE

The Tangent-Galvanometer

ATTENTION has recently been drawn more than once (notably by Sir William Thomson, and by Mr. W. H. Preece and Mr. Kemp) to the advantages offered, in certain cases of the use of the tangent-galvanometer, by placing the instrument so that the plane of the coils makes a greater or less angle with the plane of the magnetic meridian. It may not be amiss, therefore, to point out that, in 1869, M. Bertin showed that the sensitiveness of the tangent-galvanometer for strong currents may be increased and the usable range of deflection doubled by placing the circle in a vertical plane inclined at an angle of 45° to the magnetic meridian (*Annales de Chimie et de Physique*, 4th series, vol. xiv. p. 27).

When readings are taken with the current traversing the galvanometer, first in one direction and then in the other, as would always be done if accuracy were important, the expression for the strength of current is almost as simple when the coils make an angle with the magnetic meridian as when they are parallel to it. In the former case the strength of current is

$$C = \tfrac{1}{2}k \cos \alpha \,(\tan \theta + \tan \theta'),$$

where α is the (fixed) angle between the plane of the coil and the magnetic meridian, and θ and θ' the deflections of the needle from the plane of the coil due to the current in the two directions. θ is reckoned positive in the direction from the plane of the coil towards the plane of the meridian, and θ' is reckoned in the opposite direction. To determine the angle α we have

$$\tan \alpha = \tfrac{1}{2} (\tan \theta - \tan \theta'),$$

and it is probably most convenient to determine the numerical value of $\cos \alpha$ in the first expression from this by tables. If the current be adjusted so as to make the second deflection $\theta' = 0$, we have simply $\tan \alpha = \frac{1}{2} \tan \theta_1$, if θ_1 be the corresponding deflection with the current reversed. University College, London, September 30

Alligators in the Bahamas

IN Catesby's "Natural History of Florida, Carolina, and the Bahama Islands," published in the latter half of the eighteenth century, the author, usually a most accurate observer, states that the mangrove-swamps on the Island of Andros presented a loathsome appearance owing to the remains of fish having been left there, half eaten, by the *alligators*. During a fairly complete exploration of Andros, which I made in the early part of last year, I observed no traces of these animals, though, as I was not then aware of Catesby's statement, I did not make any special search for them. In response, however, to inquiries made in the local paper, I lately received from the Rev. W. L. de Glanville, Rector of Inagua, Bahamas, a letter from which the following is an extract :—

"Legendary stories of alligators having been floated to this island on logs of mahogany are numerous here. I have not succeeded in verifying any of them. On July 21, while on a visit to our North-West Point Settlement, a man exhibited to me the skin of an alligator which he had shot a day or two previously. Length all over, from tip to tip, 8 feet ; from line at right angles to tip of snout to angle of jaw, 13 inches ; greatest frontal diameter, about 11 inches.

"Logs of mahogany have been drifted recently on these shores, but no one saw an alligator arrive. That shot was on shore, and seen more than once."

As the distance from this to Inagua is more than 400 miles, I have not been able to make inquiries on the spot. But there seems to be no doubt that the alligator must have been carried by the current from the south-east on a log of mahogany or other wood from San Domingo to Inagua. It seems likely that alligators have frequently been drifted to that island, though the absence of a suitable environment has prevented their surviving. The conditions in Andros would suit them better, since about that island there is a considerable extent of fresh and brackish water in lakes, lagoons, and creeks. But it is not easy to understand how they could arrive at Andros, unless we suppose that the Gulf Stream carried them from the north-west coast of Cuba and cast them on the west side of the Great Bahama Bank, whence small local currents and the wind might bring them to the west side of Andros. The distance travelled would in this case be about 300 miles, or about twice as great as that from San Domingo to Inagua.

I trust that this note may be useful as affording further proof of the fact that oceanic currents take some part in the dispersion of even large animals. JOHN GARDINER

Nassau, Bahamas, September 15

Meteors—The September Taurids

ON September 22, 1886, 10h. 26m., I observed a fine meteor about equal to Jupiter, pursuing a path of some 7° in the extreme east region of Aries. It left a streak and moved somewhat slowly, being evidently foreshortened near its radiant point in Taurus. At 10h. 46m. the same night I noticed another meteor from the same direction.

On September 21, 1879, I counted 92 meteors, including several from this radiant in Taurus, and on September 22, 1884, two others were seen amongst 29 registered on that date.

A comparison of the paths shows a well-defined radiant at 63° + 23° (about 8° N.N.W. of Aldebaran), and I believe the shower is rather an important one, though not well visible until late in the night.

I have recognised several radiants from this position in Taurus in October and November, and in August Mr. Greg derived a shower at 64° + 22° from the observations in 1867-74, collected by the Luminous Meteor Committee of the British Association. On October 17-19, 1877, I found a radiant at 63° + 22° ; on November 20, 1876, at 62° + 22½° ; and on November 27, 1880, at 63° + 21°. There are also many other contemporary showers slightly south-west at about 59° + 20°, and it is in November that the display of meteors from Taurus reaches a maximum.

In September, during the last half of the month, I have determined some other showers in the region of Taurus, supplying meteors of much the same character. The chief additional centres of radiation seem to be at 74° + 14°, 70° + 4°, and 53° + 3°, and there is a fairly active shower also from a point further east, at 89° + 19°, in Orion. The first of these, near 11 Orionis, was splendidly defined from 8 bright meteors on September 27, 1886 ; and on September 22, 1871, Lieut.-Col. Tupman saw it at 75° + 15°. The Orionids at 89° + 19° were well seen in September 1877, and confirmed in September 1884, but this is essentially a morning shower, as the radiant does not reach a fair altitude for the dispersion of its meteors until the few hours preceding sunrise. W. F. DENNING

Bristol, October 3

Action of Light upon Diastases

IN 1878, in conjunction with Mr. T. P. Blunt (*Proc. Roy. Soc.* No. 191), I showed that the *inversive ferment* of cane-sugar is destroyed by oxidation on prolonged exposure to sunlight. Lately I have extended this observation to other ferments of the like kind, with similar result.

Twenty-five cubic centimetres of very active solutions of *malt diastase*, *pancreatic diastase*, and *trypsin* respectively were rendered inert by insolation in 50 cc. flasks for one month (August 25 to September 25).

A solution of *pepsin* was likewise destroyed, but in this case the ferment had been badly prepared, and was not very potent to commence with.

On the other hand, 25 cubic centimetres of solution of *rennet*, though distinctly enfeebled by insolation, still retained its specific properties at the end of the month. This immunity, however, was only relative, for a more dilute solution in a shallower stratum was almost entirely destroyed by one week's exposure to light (August 31 to September 7).

In all cases the contents of similar flasks kept under like conditions of temperature, &c., but in the dark, were found to be still active at the termination of the experiment.

In determining the peptonising power of the trypsin and pepsin, Grützner's method (carmine-stained fibrin) was very useful. I find, however, that it is more convenient and econo-

mical to keep the prepared fibrin by drying it in a current of air than to preserve it under ether, as usually recommended.

September 27 ARTHUR DOWNES

Note on Actinometry by Oxalic Acid

OXALIC acid is entirely oxidised by light (*Proc. Roy. Soc.* No. 191, and *Chemical News*, October 8, 1880), and affords, by reason of its own physical properties and those of the products of the reaction, an excellent medium for actinometry. A preliminary series of experiments on the physical conditions which modify this oxidation show that, *c.p.*, the effect is greater in direct proportion to the extent of exposed surface of the solution but inversely as its depth. It is greater also in proportion to the strength of the solution; and it would appear—I speak for the present quite provisionally—that in this relation the reaction follows a definite law, being *as the square root of the mass.*

September 27 ARTHUR DOWNES

Humming in the Air caused by Insects

IN a letter to the Hon. Daines Barrington (letter lxxx.) the Rev. Gilbert White, the well-known author of the "Natural History of Selborne," mentions a strange humming sound in the air. He writes:—"There is a natural occurrence to be met with upon the highest parts of our downs in hot summer days which always amuses me much without giving me any satisfaction with respect to the cause of it: and that is a loud audible humming as of bees in the air, though not one insect is to be seen. This sound is to be heard distinctly the whole common through from the Money Dells to my avenue gate. Any person would suppose that a large swarm of bees was in motion, and playing about over his head. This noise was heard last week on June 28."

It is singular that no explanation has been offered by any one for such a common phenomenon. I am convinced that the humming sound mentioned by Gilbert White was nothing more than the noise occasioned by the vibrations of millions of insects' wings in the air. In hot summer evenings in particular I have heard these peculiar humming sounds, and know them to be caused by immense hordes of gnats and midges which fill the air with their numbers. W. HARCOURT BATH

The Limes, Sutton Coldfield, near Birmingham, October

Mimicry in Snakes

A CURIOUS fact has been lately brought to my notice by a friend of mine, Mr. H. M. Oakley, in connection with the *Dasypeltis scaber*, Linn., or egg-eating snake—the "Eijer eter" of the Dutch colonists—which, if not already well known, may prove of interest to some of your readers. The specimen obtained by Mr. Oakley was caught at Hout Bay some twenty miles from Cape Town, and is about 3 feet in length, and its size, markings, and colour bear sufficient resemblance to those of the Berg Adder (*Clothos atropos*, Linn.) to be easily mistaken for that snake. It also has keeled scales, generally characteristic, at the Cape, of venomous species. Its head has, however, the long lacertine shape distinctive, here, of harmless snakes, but, when aroused and alarmed or irritated, it flattens it out until it assumes the usual viperine shape of the "club" in a playing card. It then coils as for a spring, erects its head with every appearance of anger, produces a hissing noise with its scales, not unlike the hiss of a puff adder or cobra, and darts forward as if to strike its fangs into its foe, and in every way exactly simulates the motions of an irritated berg adder. This snake has, however, neither fangs nor teeth (which, indeed, would not be required for egg-swallowing), and is not poisonous, a fact which was placed beyond doubt by Mr. Oakley repeatedly placing his finger in the reptile's mouth. This seems a clear instance of mimicry of another species for defensive purposes, but I am not aware of another instance among ophidians.

W. HAMMOND TOOKE

Cape Town, Cape of Good Hope, September 8

THE COLONIAL AND INDIAN EXHIBITION

CONTINUING our review of the most noteworthy or interesting vegetable products now being exhibited at South Kensington, we find in close contiguity to those from British Guiana, described in NATURE, July 15, p. 242, the exhibits from

Mauritius.—The entire collection, though not large, is one of some interest, and the vegetable kingdom plays by far the most important part in the exhibits. The collection of fibres will attract attention as much for its completeness as for the care with which they have been prepared. Many are of scientific interest only, being obtained from plants that could never be turned to commercial account, such, for instance, as *Hyophorbe Verschaffeltii*, *Latania commersonii*, *Lodoicea sechellarum*, *Macrozamia spiralis*, &c. This collection is exhibited by the Botanical Gardens, as is also a collection of woods of similar interest. Some notes on these woods are useful. Thus, we are told that *Tecoma pentaphylla* has a soft white wood, not much used, and that it is a moderate-sized shade-tree of rapid growth. Samples of the wood, however, grown in the West Indies, show a close and even grain, and are fairly hard—so hard, indeed, as to suggest its suitability for wood-engraving, for which purpose it has been tried in this country, and though not by any means equal to boxwood, was reported upon as likely to be found useful for some kinds of work. The soft wood of *Ficus mauritiana* is used in the colony both for firewood and for hollowing out for canoes, while the hard wood of the Ebony (*Diospyros Ebenum*), which is described as being either black or sometimes streaked with yellow and brown, is used for inlaying, furniture, and ornamental turnery. The Bois Maigre (*Nuxia verticillata*) is said to produce a short-grained timber which decomposes rapidly, but when young it makes excellent walking-sticks, which are much sought for. *Terminalia Benzoin*, a large tree, which has become scarce in Mauritius, produces a wood valued for many purposes. It would seem that the wood is sometimes fragrant, for it is said that "some parts of the tree were once much burnt in Mauritius as an incense." Another odoriferous wood is *Noronhia Broomieana*, called here Bois Sandal. The Carambole (*Averrhoa Carambola*), valued in India for the sake of its acid fruits, is planted in Mauritius for the same purpose, the fruits being eaten either raw or made into tarts.

Probably the exhibits that attract most attention in the Mauritius Court are the fine samples of vanilla pods, covered as they are with an abundant coating of crystals, and shedding forth, even through the glass cases which cover them, the delicate fragrance for which vanilla is celebrated.

Seychelles.—Amongst these exhibits the Double Cocoa-Nut, or Cocoa de Mer (*Lodoicea sechellarum*) is the most prominent. The double form of the fruit, which is its normal condition, is well shown, as well as a triple-lobed nut, which is not very uncommon. Here also are fine samples of vanilla, nearly, if not quite, equal to those from Mauritius. Dried papaw juice and some remarkably good specimens of essential oils are shown, all of which are extremely creditable to the colony.

Cyprus.—The vegetable products shown in this Court are not numerous, nor is there anything of novelty excepting perhaps a peculiar black substance described as honey, from the Carob or Locust Bean (*Ceratonia Siliqua*). The pods themselves are also exhibited, and their production, it seems, has greatly increased in recent years, stimulated by an increasing demand, especially in this country, where they are used very largely in making the patent compound cattle-foods, in consequence of their saccharine and nutritious character. Low freights have much encouraged the trade in carobs, enabling shippers to sell them at moderate prices. The quantity of carobs exported from Cyprus in 1884 amounted to 30,000 tons, about one-half of which came to England. The finest quality is produced in Limassol and Lefcara, and obtain relatively higher prices than those of Kyrenia. The average price realised for these pods is about 3*l.* per ton.

Another product of great importance to Cyprus up to

the year 1873 was madder from *Rubia tinctorum*, an article of considerable profit to landowners. It was largely used in dyeing Turkey-red yarns. The discovery of coal-tar dyes seriously interfered with the demand for madder, so that its growth has much decreased. In consequence, however, of the mineral dyes being much inferior in fastness, madder is being again sought after, and should the demand continue, there is a prospect that madder will again assume its former importance. Among other interesting exhibits, the rude native cart of the form in use for over 2000 years, and still in use, attracts much attention, as does the threshing-board, the same as was in use in patriarchal times. It is studded with flints on the under-side, and is drawn by bullocks or horses over the grain, by which means the seed is separated from the ears and the straw reduced to small particles. This is said to be the only system employed for threshing in Cyprus.

A few well-known woods, such as Olive (*Olea europea*), Cedar of Lebanon (*Cedrus Libani*), Bay Laurel (*Laurus nobilis*), Chian Turpentine, (*Pistacia Terebinthus*) are exhibited, as well as the concrete resin of the latter, or crude Chian turpentine, under the name of Trimithia gum, in curious small greenish-coloured pots.

Malta.—The Maltese exhibits will be best remembered by the fine show of lace and silver filigree work. A good show is also made of preserved fruits, and tobacco of very fine quality and varied forms is exhibited; besides these there are very few other vegetable products.

JOHN R. JACKSON

GREEK GEOMETRY

WE have before us parts 6, 7 (?), of Dr. Allman's "Greek Geometry from Thales to Euclid,"[1] in which we are brought almost into touch with Euclid. There is then but little wanting to complete the task commenced by the author in 1877, in the performing of which so much light has been thrown upon the contributions of the early Greek mathematicians to geometrical science.

In NATURE (vol. xxx. pp. 315, 316) we gave an account of Archytas and Eudoxus; the present parts commence with a discussion of the claims of Menæchmus, "pupil of Eudoxus, associate of Plato, and the discoverer of the conic sections." In the forefront are placed translations of eleven fragments which contain what is known of Menæchmus. The various points which arise are most carefully reasoned out, with considerable detail, but we cannot attempt here to compress what is already concisely given. The notes are very valuable, and show over what a wide field of reading Dr. Allman's researches have taken him. We note only the prominence given to M. Tannery's papers, as we have frequently had occasion in these pages to draw attention to this mathematician's valuable memoirs on Greek geometry. The last part (which we have numbered 7) opens with an account of Dinostratus, brother of Menæchmus, whose name occurs in connection with the quadratrix. Dr. Allman states the case of Dinostratus *versus* Hippias: "The result of the whole discussion seems to be that the quadratrix was invented, probably by Hippias of Elis, with the object of trisecting an angle, and was originally employed for that purpose; that subsequently Dinostratus used the curve for the quadrature of the circle, and that its name was thence derived." Sporus (or Porus) comes in for a mention, and then we come to Aristæus, who wrote on the conic sections, and is the author of the theorem, "The same circle circumscribes the pentagon of the dodecahedron and the triangle of the icosahedron, these solids being inscribed in the same sphere." This occurs in his "Comparison of the Regular Solids." Bretschneider thinks the thirteenth Book of Euclid's Elements is "a recapitulation, at least partial, of this work of Aristæus" (cf. also Dr. C. Taylor's "Conics," p. xxxiii.).

Of Aristæus, in closing, our author writes: he "may, therefore, be regarded as having continued and summed up the work, which, arising from the speculations of Philolaus, was carried on by his successors—Archytas, Eudoxus, and Menæchmus. These men were related to one another in succession as master and pupil, and it seemed to me important that the continuity of their work should not be broken in its presentation."

We hope another year will suffice to bring this sketch of Greek geometry to a close, and that then the author will collect these parts, whose appearances have been extended over nearly ten long years, in one volume, with such additional notes as his subsequent reading will enable him to append.

We can only commend these two parts, as we have the previous ones, to the careful study of all who are interested in these researches: they have taken a high place in the estimation of foreign mathematicians, even in cases where the author's conclusions have not been unhesitatingly accepted.

[1] The following references to the several parts may be of service:—Hermathena, part 1, vol. iii. No. 5, pp. 160-75; part 2, same number, pp. 175-207; part 3, vol. iv. No. 7, pp. 180-228; part 4, vol. v. No. 10, pp. 186-212; part 5, same number, pp. 212-235; part 6, vol. v. No. 11, pp. 403-32; part 7 (?), vol. vi. No. 12, pp. 105-30.

THE HYGIENE OF THE VOCAL ORGANS[1]

THE cultivation of the voice and the means of maintaining it in a state of excellence under the varying strain of daily life, are subjects of interest to us all, but become of paramount importance to those who are professionally brought before the public as speakers or singers. Although the laryngoscope is invaluable in the recognition and treatment of disease, it is surprising how little it has up to the present time added to our knowledge of the physiology of the larynx.

The difficulties of examining the larynx during singing are so great that a large number of singers have to be examined to obtain a complete view of the whole process by even the most expert laryngoscopist. The results of the examination of some three or four hundred persons with fine voices, including most of the best singers of the day, form not the least interesting portion of the book.

There is no question that the voice, whether the note be high or low, whether a chest or head note, whether bass or falsetto, is produced by vibration of the free edges of the vocal cords, which are two movable ligamentous bands about half an inch long stretched from back to front of the larynx. In other words, the only place where all notes, whatever their character may be, can be produced, is in the larynx.

These bands are attached anteriorly in contact with one another, but their posterior fourth is attached to the small pyramidal-shaped arytenoid cartilages, which can move laterally. The glottis, the space between them, is thus divided into a ligamentous and a cartilaginous portion. There is the greatest difference of opinion among authorities as to the position of the cords and arytenoid cartilages, and as to how much of the cord vibrates in the production of the various sounds.

Dr. Mackenzie divides the range of the voice into two registers, viz. one (chest) in which the pitch is raised, by means of increasing tension and a (consequent trivial) lengthening of the cords, as the voice sings upwards; the other (head), by which a similar result is brought about by gradual shortening of the vibrating reed, which is still tense, though less so than in the chest register. These fundamental divisions are the so called chest and head modes of production, and the falsetto corresponds to the head register of the female voice, of which it is an imitation.

[1] "The Hygiene of the Vocal Organs." By Morell Mackenzie, M.D. Pp. 223. (London: Macmillan & Co., 1886.)

Speaking generally, it may be said that the cartilaginous glottis is generally open in the lower and gently closed in the upper notes of the chest, and that a segment of the ligamentous glottis is *tightly* closed in the head voice. The two registers may be called the long-reed and the short-reed, according to the length of the cord vibrating. It has also been noticed that the blast of air is much feebler with the head than with the chest voice.

The new and important observation which Dr. Mackenzie has made and amply verified is, that in the head note of women and in falsetto singing only the anterior third of the vocal cords, as shown in Figs. 3 and 4, vibrate, and that the remainder of the cords are in firm contact with one another. Only twice has he observed a vibration limited to the middle third of the cords, which has often been described as the usual one. Some observers have asserted that in falsetto only the extreme edge of the cords vibrates; but, as 12 inches is the nearest distance at which a good image can be obtained by the

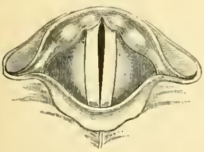

Fig. 1.—The position of the vocal cords for the lower range of chest notes.

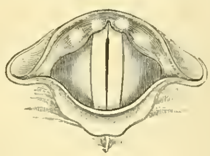

Fig. 2.—The position of the vocal cords for the higher range of chest notes

Fig. 3—The position of the vocal cords for head notes.

Fig. 4.—The position of the vocal cords for falsetto notes.

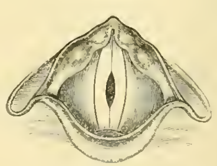

Fig. 5.—A very exceptional position of the vocal cords for head notes.

laryngoscope, only the mean position of the cords can be observed, and it is impossible to detect any vibration when a high note is being sung; and hence the author rejects the statements of those who profess to have observed vibrations limited to the edge.

The long-reed or chest voice is generally used by sopranos, Figs. 1 and 2 showing the position of the cords in the case of Mesdames Nilsson, Albani, and Valleria; on the other hand, the high notes of mezzo-sopranos and contraltos are short-reed, *e.g.* Madame Patey, as shown in Fig. 3. Tenors use both reeds, while the long only is used by the basses, and commonly by the barytones.

Alto singers among men use the short-reed, whilst boys always use the long.

In falsetto the false vocal cords, which are movable bands of tissue superior to the true vocal cords, also approximate considerably.

The quality of a voice depends upon the accuracy with which the vocal cords are moved, on their tension, on the regulation of the respiration, on the position of the soft palate and fauces, and on the movements of the tongue and lips.

These points are all touched upon, but the details of the methods by which they are to be trained do not fall within the scope of this book, but belong to the domain of the singing-master.

A certain amount of vocal discipline is recommended for children as early as the age of five or six, or even younger, but it should be limited to simple airs of limited compass, such as those by Louisa Gray, published by Messrs. Wood and Co. They are warranted to contain "no love and no high notes," and may therefore be trusted not to inflame either the infant's tender heart or its delicate larynx.

Observations on 500 choristers have disproved the idea that "cracking" or "breaking" of the voice is an essential stage, for in only 17 per cent. did the voice become cracked in changing to the adult condition; and in these cases the cords were congested, and the state was due to over-exertion or to cold.

The hygiene recommended for vocalists may be summed up in the adoption of such a mode of life as is most beneficial to the general health; prompt treatment of any cold or hoarseness; and, if their faith is pinned on the virtues of raw eggs, champagne, or any of the thousand and one things recommended for the voice, they may be permitted, if they are not absolutely injurious.

The latter part of the book is occupied with the training of the speaking voice, an account of its various defects, and the methods of diminishing them.

Stammering, which depends on a defective control over the respiration and over the tension of the vocal cords, may be much improved by training; while stuttering, which depends on a spasm of the tongue and on imperfect control over the lips, is rarely benefited, except in the slighter cases. Strychnine is occasionally of use, while tobacco intensifies the difficulty.

Valuable hints for training the voice are given, and great stress is laid on the importance of a most accurate acquirement of the vowel sounds, when the consonantal follow readily.

A NEW CASE OF PARTHENOGENESIS IN THE VEGETABLE KINGDOM

EIGHT years ago I discovered in the *Quebrada* (*i.e.* ravine) of Guarenas, about nine miles to the east of Caracas, and approximately at 650 metres above the level of the sea, one of those charming groups of tropical vegetation, which are equally interesting to the botanist and to the lover of the picturesque beauties of nature. A magnificent specimen of *Pogonopus Ottonis* was all aglow with its large rosy sepals; up to its highest branches a luxuriant *Vitis caribæa* had ascended in graceful festoons, laden with blackish grapes, and displaying now and then in the gentle breeze the silvery glimmer from the under side of its palmate leaves; whilst in the damp shade underneath throve a colony of *Gloxinia pallidiflora*, a plant which from its bruised leaves gives out a smell identical with that of the spearmint.

My attention, however, was especially attracted to a tall suffrutescent climber with dark-green ivy-like foliage, and large drooping clusters of bright-red fruits, which I was sure I had never met with before. The general *facies* was certainly that of a menispermaceous plant; but the structure of the fruit proved to be utterly discrepant from anything I knew of this family. Flowers I found none, and a prolonged search in the neighbourhood for another specimen was to no effect. I gathered a quantity

of fruits, some of which were sown in the little garden belonging to the house I inhabited at the time in Caracas. Others I sent to several leading botanists in Europe, requesting them to give me their opinion about the plant; the result, however, was negative, the fruit being to all of them a puzzle, just as it had been to myself.

Meanwhile some of the seeds had germinated; I planted out three seedlings, which grew very vigorously, and in time produced an abundance of flowers, *all female ones*. Their structure gave additional weight to the supposition that the plant belonged to the Menispermaceæ, and believing it to be a new genus, I was anxious to discover the male plant. In this pursuit the botanical interest went hand in hand with that of the horticulturist; for although the plant is highly ornamental on account of its foliage, its principal merit as a decoration in a tropical garden consists in the striking contrast between the dark-green leaves and the large number of scarlet fruits, which bear the greatest resemblance to the half-ripe berries of the coffee-tree.

For a long time all my efforts were unsuccessful. I had moreover occasion to convince myself that the plant was extremely rare in our flora, as only in two places of the above-mentioned ravine a few specimens hitherto have been found by myself and my collectors.[1]

In 1881 at last one of my men brought me a plant which he pronounced to be a male one. The plant was set between two female ones, and after a couple of months I had the great satisfaction of beholding for the first time the *male* flowers that for several years had been the object of many a fatiguing search in the dense thickets of the little river of Guarenas. Both female plants produced now a large crop of fruits, though I was unable to make out by what agency the transport of pollen was effected. Of animals I noticed on the plants only a small species of a green *Tettigonia* (rather plentiful), some common mosquitoes, and a few caterpillars of *Ophideres cacica*.[2] It is not impossible that the mosquitoes were of some significance for the purpose of fecundation. I thought once the flowers might be of the anemophilous type; but this is certainly a mistake, as they are so much hidden amongst the foliage that the wind can hardly reach them.

I sent male and female flowers, as well as fruits, to Kew, and following the advice of Sir J. D. Hooker, likewise to Prof. Eichler, of Berlin, who recognised the plant as belonging to his genus *Disciphania*, and described it afterwards under the name of *Disciphania Ernstii* in *Jahrbuch des Kön. Botan. Gart. zu Berlin*, vol. ii., 1883, pp. 324-29, giving at the same time the analytical details of the flowers and fruit on Plate XII. of the volume referred to. As this work may not be easily accessible to all who take an interest in the facts I have to present hereafter, I deem it convenient to insert a summary description of the species, giving, however, a fuller development to certain structural particulars which, in my opinion, possibly may have some bearing upon the chief point of my communication.

Like many other Menispermaceæ, *Disciphania* bears root-tubers, which are, in good-sized plants, as large as a man's fist, and weigh 1 lb. and even more. They contain a considerable quantity of ovoid starch grains, the largest measuring 0·04 by 0·026 millim. The stem exhibits the compound structure usually found in climbing plants; it soon becomes woody in its lower part, whilst at the same time the periderm increases greatly in thickness, and forms a very irregular spongy bark. The younger parts of the stem, as well as the branches, generally wind around any support they may encounter; but sometimes they climb by means of the petioles, the basal part of which is rather abruptly thickened and variously curved, so that it serves as a hook, more or less, as in some species of *Clematis*. There are other branches which do not climb at all, but either hang down without showing any sign of torsion, or run in a straight line on the soil. The cortical system is very much developed, and the central parenchyma abounds in laticiferous cells, each one containing a great many nuclei and a viscid latex.

The leaves are most singularly polymorphous on the same plant, as will be seen from Figs. 12 to 16, which are copied, as likewise all the others, from Prof. Eichler's plate. The palmatisect leaf (Fig. 16) exhibits the basal thickening and inflection of the petiole, which I mentioned before.

The flowers are strictly diœcious, and in both sexes arranged in axillary, centripetal, and drooping spikes, measuring from 8 to 25 centimetres in length. The rachis of the female spikes is very thin at the basal end, where it is scarcely 1 millimetre thick; but it increases gradually in thickness, and in many cases it measures at the opposite end 3 millimetres by 2, so that the extreme transverse sections are in the ratio of 1 to 6 approximately. Its tissue is gorged with latex, especially in the thicker part, which has an appearance as if it were due to a kind of normal hypertrophy. Not having actually any fresh male inflorescences, I am unable to say whether their rachis presents the same structure; amongst my old notes I cannot find anything referring to it.

The flowers are so crowded that they touch each other, and hide the rachis and their little bracts completely. This is especially the case towards the apex of the spikes, where not unfrequently two or three empty bracts are found, undoubtedly indications of as many suppressed or aborted flowers. Figs. 1 to 3 represent the male flower; Figs. 4 to 7 the female one. Both have six large sepals and six very small petals; in the former there are three stamens, in the latter three pistils, but in none the slightest rudiment of the organs of the other sex is to be seen. I have carefully examined hundreds of female flowers, and can most positively assert that this rule holds good in every case, nor are there on the female plants any rudimentary male flowers, auxiliary stamens, or any other contrivances that could be considered as pollen-producing organs.

Fig. 8 represents an almost full-grown fruit in its natural size; Fig. 9 is the seed, viewed from the flat side, magnified 25 times; Fig. 10 is its longitudinal section, with the straight embryo *in situ*; and Fig. 11 is a transverse section of the same. The very peculiar wings of the seed develop gradually, as indicated by the letters *a*, *b*, and *c*, in the last-mentioned figure.

I have thought it necessary to give a rather lengthy exposition of introductory matter, before entering upon the principal object of the present paper. The question of parthenogenesis in the vegetable kingdom is still strenuously objected to by many botanists, although it is a thoroughly well-established fact in the domain of zoological science, so that there is *a priori* really no reason for denying its existence in plants. It is, however, of the greatest importance to give in any particular case a most substantial and complete record of the leading facts, as well as of the concurrent circumstances, so as to enable the reader to get a full view of the matter, and form his own judgment accordingly. I hope to do the second, as far as it is pertinent, and shall now proceed to relate my observations on, and experiments with, *Disciphania Ernstii*, from which I have come to the conclusion that in this species we have really *a new case of parthenogenesis in the vegetable kingdom*.

Long before I got the male plant of *Disciphania*, I had noticed that on my female plants appeared now and then a few fruits. Very naturally the idea crossed my mind that I might have before me a case of accidental

[1] It is a singular coincidence that in one of these places another very curious Menispermacea was found, viz. a female plant of *Odontocarya hederæfolia*, Miers.

[2] The caterpillar and pupa of this beautiful moth were on this occasion described for the first time. See a note, "Jugendstadien von *Ophideres cacica*," in Karsch, *Entomologische Nachrichten*, 1885, pp. 6, 7.

parthenogenesis; I was, however, too much interested in obtaining, first, the missing sex, in order to make sure what species of plant was the subject of my researches.

In December 1881 I removed to another house, but before doing so I totally destroyed all my specimens of *Disciphania*, as I wished to begin my further investigations on two young plants which had not yet flowered. These I procured early in 1882, and, most fortunately, both proved to be females. I had some lattice-work placed against the wall of an inner court-yard, and there the plants were left to over-run the whole wall, which is 4·5 metres by 4. As soon as the flowers

Disciphania Ernstii, Eichl. (After Eichler.)

appeared I proceeded to examine them as carefully as possible, in order to see whether there were any male organs concealed either within or in their neighbourhood, but I searched in vain. In March 1883 the plants had covered the whole space allotted to them, and were then cut down. Branch after branch was once more submitted to the closest inspection, and the existing fruits, numbering 20, were collected. Of these 20 fruits I examined 5, and found that 3 had perfect embryos; 10 were sown in pots, but only 3 germinated; the remainder of the crop I still have in my carpological collection.

The plants soon began to sprout anew, and were again carefully searched whenever time and weather would allow it. They were cut off in December 1884, giving a crop of 54 fruits, which were disposed of in the following manner:—Examined, 10, 7 having perfect embryos; sown, 20; germinated, 9; kept in salt solution, 24.

The third period lasted till February 1886. Both plants were very vigorous, and had produced a large number of flowers, so that I collected no fewer than 137 fruits, of which 10 were examined (5 were good), 20 were sown, (8 germinated, the young plant being now about 6 inches high); the remainder will be sent to different botanical gardens within the tropics, in order that my experiments and observations may be repeated under the most favourable circumstances possible.

Since February the plants have grown a good deal; one is flowering and has already four fruits.

From the very outset of my observations I had noticed that these fruits appeared only on the thickened end of the flowering rachis, which is always the lowest part of the pendent inflorescence, as I have described in the first section of this paper. I cannot help thinking that this circumstance has something to do with the production of these fruits in general.

I must observe that the numbers 20, 54, and 137 of the fruits collected are not the total numbers of fruits produced by the plants in each period; for the earlier fruits fell off and got lost long before I gathered the crop. Whatever may have been this loss, it is certain that there was a constant and very notable increase of fruits. I am sorry I omitted counting all the flowering spikes at the time when the plant were cut down, so as to be able to compare their number with that of those bearing fruits, and to find out, at least approximately, whether both groups of numbers were reciprocally proportionate, or not so.

Be this as it may, *there is no denying the fact that many female plants produced in three successive years an increasing number of fertile fruits without the operation of any fertilising pollen from a male flower.*

The reader will remember that the nearest group of *Disciphania* is at a distance of about nine miles from Caracas. I am quite positive about this point, being well acquainted with the vegetation in the environs of the city. Now it is incredible that under such circumstances and in this species, which has neither showy flowers nor any perceptible smell, the pollination could have been effected by insects. It is furthermore certain that my plants of *Disciphania* are the *only* ones in Caracas, and that for this reason there is no specimen nearer to them than the few spontaneous ones which may grow in the ravine of Guarenas.[1] And even if there had been any pollination from outside, how is it that plants, which are known to be extremely prolific under normal circumstances, should produce such very scanty crops, although grown under the most favourable conditions?

For these different reasons I hold that the possibility of pollination from a male plant is entirely out of the question, and may fairly be discarded

But it is likewise impossible that pollination could have taken place with material produced by the plants themselves, as no rudimentary male flowers, nor auxiliary stamens, have been discovered on them during the most scrutinising search in three successive years; nor was there ever found one single grain of pollen on the hundreds of stigmas that were inspected in the course of this investigation. I well remembered Karsten's criticism of Alexander Braun's paper on parthenogenesis in *Cœlebogyne*, and was, accordingly, very scrupulous to establish beyond all question the absence of any pollen-producing organs. I am fully convinced that I should have found them, if any had really existed.

In another respect I was unable to arrive at a positive result. I could not make sure whether the embryo is developed as an outgrowth from a cell of the nucellus, as Strasburger has found in *Cœlebogyne*, or whether it is the development of an unfertilised oosphere. As, however, the former case appears to be always connected with polyembryony, which does not occur in the seeds of *Disciphania*, it seems to me more probable that in this plant we have an instance of the second case, or of true parthenogenesis, certainly not as the rule and normal *modus* of reproduction, but as an exception, and a very rare one, a kind of makeshift of nature, as it were, when the co-operation of the fertilising material cannot be realised.

In Prof. Weismann's essay, "The Continuity of the Germ-Plasma," there is a chapter on the nature of parthenogenesis, which abounds in suggestions which, in my opinion, throw much light on the case under consideration. I quote the following sentence from Prof. Moseley's abstract in NATURE, vol. xxxiii. p. 157:—"If a special supply of nourishment reaches the germ-plasma, this increases in amount by growth, and thus obtains the mass requisite to start the ontogenetic process, with the result that parthenogenetical development takes place." Strasburger had already pointed out that an analogous result may be arrived at by specially favourable conditions in the supply of food, which counteracts the insufficiency of the germ-plasma. May we not suppose that something similar happens in *Disciphania?* Besides the herbaceous branches, the club-shaped rachis of the spicate inflorescences abound in proteids, and consequently there must be a specially abundant supply of food, which may have some particular influence on the growth of the ovary and its contents. And it is on those places we find precisely the fruits for which I claim a parthenogenetic origin.

Caracas, June 7 A. ERNST

P.S.—Since the foregoing article was sent to England, I have made the following observation, which, I think, gives additional strength to my view as to the probable cause of parthenogenesis in the case under consideration. On one of my plants I had noticed two rather short inflorescences (4 and 5 centimetres long), with but 3 and 4 flowers respectively, *but having a very much thickened, almost club-shaped, rachis*, which measured at the apex nearly 3 millimetres each way. The idea struck me that on these spikes very likely some fruits would appear, and I marked them out for the sake of further inspection. *My anticipations have been fully realised*, as on each of the two there is now one ovary increasing in size, measuring already 3 millimetres by 2, so that there is every reason to expect their final development.

At the same time I may mention that on the second plant, which has just begun to flower, I have found on one spike a *tetramerous*, and on another a *pentamerous*, female flower; both spikes were very small, and had only two flowers. A. ERNST

Caracas, June 23

[1] It is interesting that the second species of *Disciphania* (*D. lobata*, Eichl.) appears likewise to be an exceedingly rare plant, as may be inferred from an observation of of Prof. Eichler's, in the article mentioned before.

OUR ENGLISH TEMPERATURES

A PERIOD of warm weather, lasting for three weeks, set in over the whole of the United Kingdom about August 24, and continued until September 14, over nearly

the whole country. Throughout this period there was no part of England in which the temperature was not above the average in each week, as shown by the returns issued by the Meteorological Office.

The persistent low temperature which preceded this warm weather, and which had so long continued, was described in NATURE for August 12 (p. 341). This cool weather continued till August 23, when, fortunately, the conditions entirely changed, and a warm spell of exceptional length for either summer or early autumn set in. It is necessary to go back to February 1885, eighteen months ago, before we find so long a period with the temperature above the average, and since that time there have not even been two weeks in succession which were warm generally over the whole country.

In recent years there has been but very little really settled warm weather during the three months July to September. Last year there was only one week, ending July 27, which could in any way be termed warm generally over the country during the whole period of three months. In 1884 finer weather was experienced, and there were four consecutive weeks, ending August 25, with the temperature above the average over Great Britain; there was also a period of three consecutive weeks, ending September 29, with warm weather, and two consecutive weeks ending July 14. In 1883 there was only one week, ending September 24, in which the temperature was above the average over the whole of the British Islands, but there were other weeks during the three months in which the temperature was high in several districts; there was, however, no continuous warm weather. In 1882 the week ending August 14 was the only instance with the temperature generally above the average, and in this period a deficiency was shown in the East of England. In 1881 there was not a single week in the three months with the temperature generally above the average. In 1880 there were five consecutive weeks, ending September 13, with the temperature above the normal value, and warm weather was also enjoyed in the week ending September 27. In 1879 temperature was continuously low throughout the period, and the deficiency generally amounted to several degrees; there was not a single district over the whole of the United Kingdom with the temperature above the mean for a single week.

From this it is seen that during the last eight years there were but two years, 1880 and 1884, which can in any way compare with this year for warm weather during the three months referred to, and in the remaining five years there was not a longer period than a single week with continuous warm weather.

The varying conditions with which warm weather occurs in England is exceedingly puzzling. This year it has accompanied weather of a cyclonic type, and has changed to cooler weather with the anticyclonic conditions which set in about September 14. To attempt an explanation of these conditions from observations for our own limited area, or even from the observations over Europe, would be but labour lost. For such an inquiry it is necessary to wait the issue of the synoptic charts for the northern hemisphere which are compiled by the United States Signal Service from the international synchronous meteorological observations. Doubtless a careful study of these will throw some light on the cause of the prolonged irregularities in the distribution of temperature.

CHAS. HARDING

NOTES

THE American Association at the Buffalo meeting unanimously passed a resolution expressing its gratification at hearing of Dr. Gould's proposed revival of the *Astronomical Journal*, and its good wishes for its success.

MR. G. T. PRIOR, B.A. of Magdalen College, Oxford, has been appointed an Assistant in the Department of Mineralogy in the British Museum, to fill the vacancy caused by the death of Dr. Flight. The two vacancies in the staff of the Zoological Department occasioned by the resignation of Mr. E. J. Miers on account of ill-health, and Mr. J. J. Quelch, appointed to the curatorship of the Demerara Museum, have been filled by the nomination after competitive examination of Mr. C. J. Gahan and Mr. Randolph Kirkpatrick. Mr. C. G. Crick has lately been appointed an additional assistant in the Department of Zoology.

WE regret to learn of the death of Dr. Clement Mansfield Ingleby, at the age of sixty-three years. The death is also announced of Admiral Bedford Pim.

WE regret to note the death of Prof. H. A. Bayne, Ph.D., of the Royal Military College, Kingston, Ontario, Canada. Dr. Bayne was a native of Nova Scotia. He graduated in Arts at Dalhousie College, Halifax, N.S., and afterwards spent five years in the special study of chemistry under Wiedemann at Leipzig, Bunsen at Heidelberg, and Dumas at Paris, taking his Doctor's degree at Heidelberg. Returning to his native land he first engaged in organising the Scientific Department of the Halifax High School, acting at the same time as Lecturer on Chemical Analysis at Dalhousie College. In 1879 he was appointed Professor of Chemistry at the Kingston Military College, which had just been founded. His work at Kingston was very onerous, and during the first few years of his professoriate he found little time for original research. At the last meeting of the Royal Society of Canada, of which he was a Fellow, he read a paper of practical value on chemical tests of the purity of silk. He had begun in Germany a series of experiments on the properties of certain of the rarer metals, in which he had been interested by Bunsen; and he hoped to continue them when leisure came. But he has been cut down at the very threshold of his work.

THE annual Exhibition of the Photographic Society was opened to the public on Monday.

NEWS of earthquakes and volcanic eruptions continues to arrive from all quarters. The North American earthquakes have not ceased. Three slight shocks were felt in Summerville on September 28, and at night several more occurred. From various parts of Central Germany, principally Thuringia, news arrives showing that in the night of the 27th, or morning of the 28th ult., there was a series of more or less violent shocks of earthquake. At Gera and other places in Thuringia, the windows, doors, cupboards, and other movable articles of furniture, were violently agitated, shaking and rocking to and fro. A despatch received at New York on Tuesday from Mexico states that a high hill in the vicinity of Chimalapa has been completely riven in two by the action of subterranean forces. The volcano of Colima, in Mexico, is in a state of eruption for the third time within a year. Information has been received at Lerwick stating that two shocks of earthquake had been experienced at Baltasno, Unst, Shetlands, on Monday night. The first shock was felt at eleven, the other two hours later. Several people were roused from sleep by houses trembling and china rattling. Both shocks lasted several seconds, but no damage occurred to property. A telegram from Melbourne, October 5, states that a volcanic eruption has occurred in the island of Niapu, in the Tonga group. Two-thirds of the island are completely covered with volcanic dust. Mount Pabloff, 300 miles south of Kodiak, in Alaska, is in eruption.

MR. S. K. SEKIYA writes from the Imperial University, Tokio, Japan:—"On July 23 quite a destructive earthquake visited Shinano, Echigo, and the neighbouring provinces, over-

throwing several houses, forming fissures on roads and hill-sides, and causing severe damage to household property. The shock also stopped the flow of a hot spring at Nozawa. The part most severely shaken lies among the mountainous district some 3000 feet above the sea, with the famous active volcano of Asama, besides many extinct ones—an interesting case in Japan, as most of the larger earthquakes extend along the sea-shores."

A RECENT number of the *Japan Weekly Mail* contains a short account of a night ascent of the active volcano Asamayama. The party left Karnisawa in the afternoon, and commenced the ascent from the eastern side about sunset. The sky was perfectly clear, and the summit was reached an hour before midnight. The wind, blowing from the south, carried the sulphurous vapour away to the northwards, and thus the ascent was made less uncomfortable. The party saw quite to the bottom of the crater, which presented the appearance of a furnace filled with glowing coals. The sound of the roaring, hissing, and bubbling is described as loud and awful. The walls of the crater are of a light-brown colour, and are composed of successive layers marked out with striking regularity like the seats in an amphitheatre. Allowing ten of these layers to each interval of 20 feet, the depth from the surface to the incandescent matter would appear to be 200 feet. The periphery of the crater is about half a mile, although the Japanese calculate it at two miles and a half.

MR. PERCY SMITH, Assistant Surveyor-General of New Zealand, has made an ascent of Tarawera, where the eruption recently took place. He found the mountain split across, the crack in some places being 5 chains wide. Mr. Smith is now making a minute examination of the district.

ACCORDING to intelligence received at Hamburg, advices from the waters of Spitzbergen now confirm the former news from Iceland and from the mouth of the Pechora, on the Siberian coast, to the effect that the ice in the Arctic Sea has this year extended unusually far southwards. Spitzbergen, the sealers report, was found to be surrounded with an ice-belt 5 to 8 miles broad, and there was firm pack ice from Hope Island to Forland, about 56 miles. The great bays on the Storfjord, Hornsund, Bellsund, and Isfjord were quite inaccessible, and the sealers, after waiting all the spring and most of the summer, returned at the end of August, as there was no prospect of the Polar ice dividing.

PROF. ALEXANDER, who has filled the Chair of Engineering at the Imperial College of Engineering, Tokio, for a number of years past, and who is about to leave the country, has been presented by his colleagues, past and present, with a handsome pair of bronze vases, inlaid with silver, and with an address. The graduates of the college on the same occasion presented him with four pieces of Japanese bronze work. The documents accompanying these presents show that the retiring Professor is much regretted by those whom he leaves behind—colleagues as well as pupils.

ACCORDING to the Report of the Superintendent of the Government Museum at Madras for the past year, the interest of the people in that institution is on the increase. The number of visitors is considerably larger, this being especially noticeable in the case of women and girls, which probably indicates some relaxation of the custom of seclusion, and an increasing interest on the part of Indian women in things beyond, and different from, their ordinary duties. In the work of the Museum there seems to have been an advance in almost every direction. The materials for catalogues of the departments of ethnology and antiquities were collected. Mr. Davison, the well-known Indian ornithologist, was engaged at the suggestion of the Governor for a period of six months to make a collection of South Indian birds for the Museum, and when this has been done a catalogue of the birds will be taken in hand. Similarly in other departments the work of the institution has been progressing. The Superintendent notes that the native visitors object to the drinking-fountain in the grounds, owing to the resemblance that the discharge of water from the mouth of a stoneware lion's head has to the act of vomiting!

THE total railway mileage of the United States is now 130,334, of which 12,116, or 9·2 per cent., is narrow gauge, and 187 broad gauge (5 feet and over). In view of the numerous breaks of gauge, transfer-apparatus enabling quick and easy change under car-bodies of trucks made for one gauge to trucks made for another is a desideratum. A committee of the Franklin Institute has just highly commended Ramsay's system for the purpose. In this, when, *e.g.*, a broad-gauge car is to be transferred to a narrow-gauge line, the car is brought with the aid of side trucks and cross bars over a depressed piece of line having both gauges, and an inclined approach and exit; and it there exchanges one kind of truck for the other. It may be noted that the narrow-gauge system in the United States, far from having "seen its best days," is constantly resorted to in the development of mountainous and sparsely populated districts, California taking the lead in this respect.

WE learn from a French source that Prof. Place, of the Cavalry School of Saumur, has recently applied electricity with great success to horses which prove refractory while being shod. It is known that a vicious beast will often give much trouble in the operation of shoeing, and may even have to be bound and made to lie down. M. Place's method renders it at once tractable, and permanently cures its aversion to the forge. The electric shock is given through a bridle of special form, from an induction-coil actuated by a dry pile.

THE effect of muscular exercise on the temperature of the body has been recently engaging the attention of M. Mosso in Italy. In thermometrical relations the nerves, he concludes, have much greater action than the muscles. Strong emotion will raise the rectal temperature of a dog 0°·5 to 2°, and the same with man. Pain has the same effect. During a walk of two days, M. Mosso observed that his temperature was not in proportion to the work done by his muscles. When dogs rest after long fatigue, one observes that their heat sinks below the normal level, though their muscular exertion has been great. Again, take the evidence of strychnine and curare; the former of which affects the nerve-centres, while the latter paralyses the muscular system. A frog poisoned with curare falls into complete paralysis, with lowering of heat. If a few milligrammes of strychnine be then injected, the paralysis does not cease, but the temperature immediately rises. Internal temperature, then, seems to depend chiefly on the nerve-centres and their greater or less excitation.

WE have received the "Proceedings and Addresses" at the Sanitary Convention held in March last in Howell, Michigan, under the direction of the State Board of Health. The various papers are of a very plain and practical character, free for the most part from technicalities. We have read with especial interest, in view of recent discussions in this country, Prof. Barnes's address on the sanitary conditions and needs of American schools. Speaking of the complaint in England that owing to the requirements of the present code the children of the very poor whose food is bad and insufficient become afflicted with sundry dangerous nervous disorders, Prof. Barnes says that if this be true for England, it certainly is not for the United States. But there as well as here there are critics who hold the system of education to be responsible for all the ills of youth. Prof. Barnes shows that this is absurd. Adequate heating and ventilation he regards as the chief respects in which American

schools are lacking. Indeed it appears from the papers that the other public buildings of the State of Michigan share these defects with the schools; the court-house, according to Mr. Waters, is little better than a death-trap, and the others are far from being what they should be.

WE have received the *Report and Proceedings* (vol. i. part 1) of the Bristol Naturalists' Society. The former is very satisfactory, as it shows an increase in the membership and an increased attendance at the meetings. The finances, too, are in a sound state, with the exception of the special library fund, which appears to be in debt. The Council urge the formation of similar Societies in neighbouring towns, and their affiliation to the Bristol Society, "for so much can be done for science by mutual intercourse and encouragement." The contents of the *Proceedings* (the part being profusely illustrated) reach a high standard. Prof. Lloyd Morgan publishes the third and fourth parts of his "Contributions to the Geology of the Avon Basin," dealing with the Portbury, Clapton, and Portishead districts. Mr. Wilson, Curator of the Bristol Museum, gives the history of the exploration of the bone-cave or fissure in Durdham Down, from which the series of mammalian remains in the Bristol Museum were obtained. Lists are given of the remains found, and of the principal publications referring to them. Mr. Bucknall publishes Part 9 of his "Fungi of the Bristol District," while Mr. Griffiths writes on the *Cicada septemdecim*, "the seventeen-years' locust" of America. There are several other more general papers. At the end is the continuation of the "Flora of the Bristol Coal-Field," edited for the Society by Mr. J. W. White, the compilation of which was commenced seven years ago, and which has continued steadily ever since. One thousand and three species have already been treated as inhabitants of the district. The present part, which is the sixth, treats of *Glumiferæ Gymnospermæ* and *Cryptogamæ Vasculares*. It is proposed to begin at once revising the earlier parts with a view to the preparation of a second edition, and an appeal is made to members and friends to aid in making the work as complete and accurate as possible. It is hoped in this way to lay before the Society a thoroughly worthy account of the botanical wealth of Bristol.

THE Otago Acclimatisation Society have, during the past year, been highly successful in their fish-culture operations in New Zealand. The utmost is being done to naturalise Salmonidæ to the waters of that country, and from all accounts the experiment is likely to succeed. The Society are about to try the experiment of retaining salmon in fresh waters at Marshall's Creek with a view to testing the assertion that it is not a physiological necessity for fish to repair to the sea to render them capable of reproduction.

NEWCASTLE-UPON-TYNE Free Library, though suffering from a fire which arose from the flue of a sunlight in the reference room getting overheated, and caused both reference and issue department to be closed for many days, nevertheless records general prosperity, boasting at the same time the issue of the smallest percentage of fiction of twelve of the largest free libraries in England. A new catalogue of 10,000 books added to the lending department during the five years and a half the library has been open, and another of the juvenile department, are being prepared to meet the want that must be so urgent in a library where crowded applicants can gain knowledge of the treasures offered them by no other channel. Only thirteen volumes, not worth 1*l*., have been lost during the same length of time, not reaching 1 in 100,000 issues; in the juvenile department only 1 in 185,000; and during the past year not one volume! Yet, as if this were not satisfactory, the Committee have decided to make every borrower (*i.e.* over 8500 persons) renew his ticket yearly, instead of once in five years, for the sake of correcting addresses. Balancing this enormous aggregate of trouble to the public, *plus* that of the library officials in carrying it out, against that of the latter in tracing borrowers who have removed without signifying the same to them, we cannot think that this shows either the wisdom of the serpent or the harmlessness of the dove! Science and other educational classes, so aptly carried on under a free library committee, were attended by 141 students in 1884–85, and, we are glad to see, by 186 in 1885–86. Three branch reading-rooms, however, we note with surprise, were not attended sufficiently to make it worth the expense of keeping them open.

THE intelligent community of Watford, to whose various clubs and classes, all working together under one committee, we called attention some time ago, find co-operation so successful that they have published a bound hand-book of 160 pages, containing, besides a library catalogue with supplementary lists down to September 1886, all the other varied information which they have to lay before the public. The principal item to notice is that they have succeeded in adding the University Extension lectures to the numerous branches of art and science already under their care. The name of "The Free Library 'College' of Science, Art, Music, and Literature" has now been adopted, as denoting the "collection" of schools of which it consists. Sir John Lubbock has accepted the new office of President of it, and on Tuesday, the 28th ult., he delivered an opening address. He chose the subject of ants and their ways; and, since natural history is among the scientific pursuits of the college, it was both a specially fitting and, we need not add, a generally interesting subject. The nucleus of all the various work carried on at Watford is a free library rate which even now only brings in 240*l*. a year. Such success should therefore encourage such smaller towns as cannot find separate committees each with its own work and expenditure also.

AMONGST the papers read at the International Congress of Orientalists at Vienna were one by Dr. Stein on the Hindu Kush and Pamir in Iranian geography, and one by Prof. Kuhn on the Indian dialects spoken in the Hindu Kush. Prof. de Lacouperie also read a paper on the aboriginal languages of China.

MESSRS. SPON have in the press: "Metal Plate Work, its Patterns and their Geometry," by C. T. Millis, M.I.M.E.; "A Practical Hand-Book on Pump Construction," by Philip R. Björling; "Spons' Mechanics' Own Book" (second edition); "Quantity Surveying," by J. Leaning (second edition, revised and enlarged); "A Treatise on Secondary Batteries," by Prof. Silvanus P. Thompson, D.Sc., B.A.

THE additions to the Zoological Society's Gardens during the past week include a Mona Monkey (*Cercopithecus mona*) from West Africa, presented by Mr. W. P. Hewby; a Malbrouck Monkey (*Cercopithecus cynosurus*) from East Africa, presented by Mr. Lionel R. Crawshay; a Rough Fox (*Canis rudis*) from British Guiana, presented by Capt. J. Smith; a Hairy-rumped Agouti (*Dasyprocta prymnolopha*) from Guiana, presented by Mrs. Otto Fell; a Common Hedgehog (*Erinaceus europæus*) British, presented by Madame Tina Mazzoni; two Moorhens (*Gallinula chloropus*), British, presented by Lord Moreton, F.Z.S.; a Horned Viper (*Vipera cornuta*) from South Africa, presented by Mr. C. B. Pillans.

OUR ASTRONOMICAL COLUMN

PERSONAL EQUATION IN OBSERVATIONS OF DOUBLE STARS.—M. Bigourdan, of the Paris Observatory, has taken the above as the subject of his Thesis for the degree of Doctor of Physical Science. In an historical review of the subject he refers to the labours of Dawes, W. Struve, O. Struve, Dunér, O. Stone, F. R. Helmert, and T. N. Thielo. He dwells particularly on the researches of

O. Struve, who has persevered so assiduously in the observations of artificial stars initiated by W. Struve. M. Bigourdan shows, however, that by this method it is not possible to eliminate the errors due to the instrument itself, and especially to the object-glass. But it is M. Bigourdan's opinion that it is difficult, if not impossible, to avoid the employment of artificial stars in determining personal equation in measures of double stars, and he has accordingly devised an apparatus, which he describes as simple and of moderate cost, by means of which observations of artificial stars can be made at any time, and which he considers to be free from the objections which have been urged against Struve's method. In this apparatus the plate pierced with holes which form the images of the "stars" and the viewing lenses, are carried by one tube which is movable round a horizontal axis, so as to vary the inclination of the eyes with respect to the horizon; the pierced plate rotating in its own plane so as to vary the angles of position of the artificial coupler. M. Bigourdan gives in the Thesis a great number of measures made with this instrument, deduces a formula for his personal equation in position-angle, and shows how the application of the corrections deduced from it improves the observations.

Publication der Astronomischen Gesellschaft, No. XVIII.—This is a paper by Herr Romberg, of Pulkowa, containing the approximate positions of stars whose places (chiefly as comparison-stars for observations of planets and comets) are given in vols. lxvii. to cxii. of the *Astronomische Nachrichten*, arranged in order of right ascension and reduced to the epoch 1855. This work is a continuation of a similar one executed by Schjellerup for vols. i. to lxvi. of the same periodical, forming No. VIII. of this series of publications, and is similar in form to it. The right ascensions are given to seconds of time, and the declinations to tenths of a minute of arc, and Herr Romberg expresses a hope that his Catalogue may be useful not only as an index to such a large number of observations of stellar positions, but also as a groundwork for accurate determinations of the star-places. The total number of stars in the Catalogue is about 8000, the great majority of them being fainter than the seventh magnitude.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1886 *OCTOBER* 10–16

(For the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on October 10

Sun rises, 6h. 17m.; souths, 11h. 47m. 1·6s.; sets, 17h. 17m.; decl. on meridian, 6° 43′ S.: Sidereal Time at Sunset, 18h. 34m.

Moon (Full on October 13) rises, 16h. 37m.; souths, 22h. 19m.; sets, 4h. 11m.*; decl. on meridian, 4° 7′ S.

Planet	Rises	Souths	Sets	Decl. on meridian
	h. m.	h. m.	h. m.	° ′
Mercury ...	7 7	12 20	17 33	9 57 S.

GEOGRAPHICAL NOTES

At a recent meeting of the Anthropological Institute in connection with the Colonial and Indian Exhibition, Mr. Pryer, of the Civil Service of British North Borneo, read a paper on the natives of this region. The main race, the Dusuns, are in all probability descendants of a mixed aboriginal and Chinese ancestry, and as we come nearer to the coasts the sub-tribes mix and blend with each other and with aliens, till on the east coast there is very little of the native type left at all, a race rapidly springing up there of very cosmopolitan origin. On the west coast there are more natives and fewer aliens, but much the same thing is occurring there on a smaller scale. It is difficult to say where the Dusun ends and the Dyak proper begins; the former were at one time head-hunters, but they are now settling down under the North Borneo Company quietly to rural toil. They are thriving and increasing, and there is no fear of their melting away and disappearing, as so many races have done when brought in contact with the white man. The same may be said of the sea-coast races, especially of the Bajans. The Sooloos are the principal fishermen, and, like the rest, are now settling down to a more quiet and orderly life. The first true tribe of the interior arrived at from the east coast is the Booloodoopy, a somewhat singular people, many of them having strangely Caucasian features, or, at all events, departing largely from the ordinary Mongolian type. Mr. Pryer describes several other tribes of the interior, and he inclines to the idea that the Chinese type is far more predominant in Borneo, even amongst the Dyaks, than has generally been supposed. He does not think that the Chinese went over in bodies to North Borneo, but rather that in the long course of Chinese trade with and settlement in the island, a slow and steady infiltration of Chinese blood, though not of Chinese speech or manners generally, took place.

At a late meeting of the Paris Geographical Society M. Hamy made a communication on an exhibition of collections from the French possessions in West Africa in the Jardin des Plantes, contributed by the Museum of Natural History and that of Ethnography. The exhibition, he said, was composed of two sections, one devoted to natural history, the other to ethnography. The first showed that the countries were rich in iron and copper, which had ever furnished the natives with indispensable implements and utensils. Trees and various plants abound, and game is not rare. Numerous races live and have lived in these regions. The exhibition shows how they are at present distributed in West Africa. There are four groups of Negroes:—(1) The Negrillos or Pygmies, the most western race. They live now only in small scattered colonies in the most unhealthy spots, such as the estuary of the Ogwe, and the interior of Mayonbo; they are called Okoa, Bongoa, Bakké-bakké, Babonko, &c. (2) The second group is brachycephalous, of middle height, and lives principally on the right bank of the Lower Congo, but particularly on the Loango. They work in iron, and are far advanced in the mechanical arts. (3) The Mpongos, or people of the Gaboon, who have been in contact

with Europeans since the end of the sixteenth century. M. Hamy referred in detail to the manners and industry of this people. (4) This is a slightly heterogeneous group, consisting of the Obambas, Ondumbas, &c., who live in the neighbourhood of Franceville. In conclusion the speaker referred to the interest of ethnological research in relation to the movements of peoples on the earth's surface. Here, he said, ethnography is especially bound up with geography.

THE Portuguese explorers, Col. Serpa-Pinto and Lieut. Cardoza (according to the *Colonies and India*) recently left the Cape Colony for Lisbon. These gentlemen have accomplished a most important scientific exploration in the Lakes region. Leaving Mozambique, they proceeded by land to Ibo, correcting many errors that had crept into the charts. From Ibo they advanced to Nyassa at the head of an Expedition 800 men strong, making as they went a geodetical triangulation of the country, using instruments of great precision. Col. Pinto, in consequence of a dangerous attack of illness, was obliged to leave the Expedition in Mebe's country, of which he had made a geological survey, occupying a long time. Lieut. Cardoza, who had been blind for fifty days, happily recovered his sight in time to take the command of the Expedition, continuing the work to Nyassa, from whence he went to Shirva and Blantyre, and by a new road to Quilimane. The whole party suffered from hunger on the way; all the dogs died of starvation, and the men narrowly escaped the same fate. The Expedition was accompanied by 200 Zulus, who rendered splendid services, being conspicuous for their courage and devotion. Besides their scientific work, the first of the kind done in that part of Africa, the leaders of the Expedition extended the Portuguese dominion over all the important chiefs visited during the journey, lasting twenty months. Everywhere the Expedition was heartily welcomed by the natives, the only place where the Mission was not cordially received being, it is said, the Blantyre Mission Station.

THE September issue of the *Scottish Geographical Magazine* contains a paper by Prof. Meiklejohn on the history, poetry, &c., in geographical names. Mr. Murray, of the *Challenger* Expedition, reviews the existing state of our knowledge of the Antarctic regions *à propos* of the project for exploring them. The Council have unanimously resolved to support any movement having for its object the careful exploration of the Antarctic regions, "as being certain to result in large and important accessions to our knowledge in geography, oceanography, meteorology, and other branches of physical science." They think the expedition should be undertaken at Government expense, but the co-operation of Australasian Governments might be invited. They suggest a conference of delegates of the leading scientific Societies to draw up a memorial to the Government on the subject.

ACCORDING to the latest intelligence received at Zanzibar from the interior of Africa, Dr. Wilhelm Junker, the African traveller, was at Msalala, south of the Victoria Nyanza, and was about to start for Zanzibar. Emin Bey was still at Wadely, and was in urgent need of supplies of ammunition and stores. The King of Uganda had murdered all the English and French converts, and the missionaries were in great danger and had asked for assistance.

PROF. BLUMENTRITT contributes to the last number of *Globus* (vol. l. No. 14) an interesting article on the Manguians of the island of Mindoro, in the Philippines, based on a Spanish work by Don Morera on the geography and natural history of that archipelago. Next to Luzon and Mindanao, Mindoro contains the greatest number of wild tribes. Those which live on the coast and along the banks of the rivers are known under the general name of Manguians, while the Bangot inhabit the plateaus, and the Buquil and Beribi have their villages amongst the high mountains of the interior, but these names vary greatly in different parts of the island. They exhibit a mixture of various races. Besides the Malays, there is Negrito blood in the Buquils, and in some places traces of Chinese descent also. Prof. Blumentritt confines himself to describing the manners, customs, dress, &c., of the Manguians. Incidentally, however, the paper tends to show the enormous complication and difficulty of ethnological questions relating to the Philippine Islands. The constant mingling of different races from China, Malaya, and parts of Melanesia and Polynesia has created a mixture of which the component parts are almost undiscernible. The vast variety of names given to tribes, which rarely mark any ethnical distinction, and which sometimes are given to the members of the same tribe, add to the confusion.

NOTES ON VESUVIUS FROM FEBRUARY 4 TO AUGUST 7, 1886

IN NATURE (vol. xxxiii. p. 367) I gave a description of the changes that had taken place in Vesuvius during the preceding months, and of the eruption of February 4. The lava that issued on that occasion continued to flow in abundance until the 11th, forming a brilliant streak on the northern slope of the cone. After that date the output of fused rock varied at intervals till about the end of the third week in March, when the outflow stopped.

On April 21, at about 5 p.m., lava rose from that portion of the fissure crossing the great crater plain on its south side, and which was the one by which the eruption of May 2, 1885, had taken place. The quantity that oozed out was comparatively small, and sufficed only to flow down the side of the great cone for about 100 metres, so as to just cover the point of exit of the lava that had issued from the same fissure in the spring of 1885. The new lava piled itself up into a kind of boss, and thus soon plugged its own passage.

A few days after, that is, on April 27, a new outburst occurred, again at a weak point—the upper limit of the fissure of 1881–82, above the buttress of lava formed subsequent upon that eruption. This was sufficient to carry off the overflow for some weeks. Slight variations, such as are constantly going on, were observable in the activity of Vesuvius and the outflow of its lava during the whole of the month of May. During the eruption of Etna, Vesuvius did not show the slightest sympathy—just what we should expect when our conception of a lateral outburst is that it is simply a mechanical result of changes that proceed in the upper part of the volcanic chimney, and usually of the mountain itself.

During the month of June the outflow of lava on the eastern side persisted, adding to the great boss, hump, or buttress formed during the years subsequent to the eruption of 1881–82. Owing to the height of the lateral outlet, and probably also from its narrowness, the level of the lava column in the chimney was very high, and, as a consequence, the numerous pasty lava-cakes added much to the size of the eruptive cone, which grew so rapidly during the month as to cover all the old remnants of crater-rings except a small portion of the northern rim of that of 1881–82. On June 29, when I visited the crater, I found a long continuous fissure extending right across the great crater plain in a westerly direction, and emitting an abundance of hot air, HCl, with vapour of chlorides, which were deposited in feathery bunches on the cooler edges of the fissure. This fissure no doubt corresponds to the upper limit of a radial dyke, as did the one existing for many months previous to the eruption of May 2, 1886, and probably does, like that one, indicate the direction of an eruption at some future time. When such an eruption takes place it will be unpleasant for the funicular railway, which, although a little south of the line of fissure, would be within reach of the outburst. In the above-mentioned visit it was possible to watch the eruptive mouth for some time from the edge of the cone of eruption, and to take an instantaneous photograph of it amidst an exciting bombardment of stones, not dangerous for one's self, but unfavourable to an inactive photographic camera. Unfortunately an accident happened to the negative, but I have since been successful in obtaining a permanent record of the eruptive mouth, though hardly such a successful picture. The diameter of the main vent was about 3 or 4 metres, and nearly circular.

The crater was again visited on June 5, but no marked change had taken place, and lava was always issuing on the east side and flowing first to one side and then to the other, always adding to the great buttress.

The cone of eruption, owing to its great increase of size during the last thirteen months, formed a very conspicuous mound, perched as it were on the flattened summit or crater plain of 1872, which truncates the great cone of Vesuvius. On June 28 it was observable from Naples that the cone was falling in, and the spine or boss forming the northern boundary of the crater of eruption had in part disappeared, and owing to the plugging of the passage the smoke only escaped in puffs. This crumbling in of the crater walls was no doubt due to the loss of

support of the column of lava within the chimney. This lowering of level probably produced the extension outwards of the eastern dyke, and the lateral outlet of lava was consequently lowered. This was confirmed by the much increased outflow of lava coincident with the falling in of the cone.

During the first week in July the volcano appeared from Naples to be very quiet; indeed, less vapour was escaping from the summit than at any time during the last seven years. From time to time the vapour was, from the gradually increasing pressure, able to burst its way through the loose materials that choked the outlet, when a puff of smoke would be visible of a dark purplish-black colour, due to its being charged with volcanic ash derived from the churning up and trituration of the lava fragments, scoria, and lapilli it had to traverse in its escape. At the same time a slight reflection was to be seen at night, indicating that the lava surface, although lowered, was not so to any great extent.

On this day, July 8, the lava which had always been gradually advancing, had crossed the southern end of the Val d'Inferno, and flowing down one of the wooded ravines on the property of the Prince of Ottajano, where it destroyed a number of trees, it continued its course, overwhelming some vine-gardens. On July 12 the number and quantity of the black smoke puffs was very great, and the crater was in the full ash-forming stage, and towards night the vent had been considerably cleared, so that the reflection was well marked. The next day the smoke issued freely and uncharged with ash. The change that took place on the 12th was no doubt due to the lava rising in the chimney consequent upon the lateral outlet getting choked; as on the 11th, the abundant flow of lava became very much diminished.

On July 20 the puffs of dark smoke again appeared, indicating a return of the crumbling in of the crater; this was again due to the lowering of the lava level, and, as was expected, the fluid rock issued in great abundance the following day, again destroying trees and vine-gardens. The next day the lava was still flowing in abundance, so as to form a bright streak on the slope of the great cone. The outflow continued to gradually diminish until the 30th, the crater above remaining inactive. On the latter date, however, the lava rose again sufficient within the chimney to cause the vapour to find a passage through the materials choking the main vent, so that on that day the puffs of black smoke were again abundant, and accompanied by the ejection of partially triturated subangular old lava and scoria fragments. In the evening bright bursts were well marked, showing that the vent was again cleared. The two following days the volcano maintained the third degree of activity (*Rep. Brit. Assoc.*, 1885, p. 395).

During the first week of August the lava again flowed rather freely from the mountain's side, whilst from its summit hardly any vapour escaped except from time to time a puff of black smoke. On August 7 a visit was paid to the crater. The cone of eruption has been reduced in height about 30 metres, and its remnants form a low crater ring inclosing a crater of oblong form having a diameter of about 80 × 60 metres. Its greater axis lies in a line from about E.S.E. to W.N.W., and its bottom is double, so that it seems to result from two craters closely overlapping each other. The crumbling-in process was still going on, and the trituration of the loose stones and the charging of the vapour puff by the ash or sand could be watched from a distance of a few yards. I was successful in obtaining two ordinary and two instantaneous photos of the interior of the crater, only the eastern half of which, however, was active.

The principal facts that may be gathered from the study of the phenomena of Vesuvius during these few months are rather confirmations of what the author has described as the mechanism of lateral eruptions, which may be summed up thus. The lowering of lava level within the chimney due to a lateral outlet removes the support the former gave to the walls of the crater and vent, which in consequence tumble in and choke more or less of the main outlet. Next the vapour contained in the lava may be compelled to escape laterally, but has a natural tendency not to do so, but rather to seek its path straight upwards. If the lateral outlet becomes choked, the lava immediately commences to rise in the chimney, and the escaping vapours burst through the loose materials in the chimney in puffs, grinding and triturating them, carrying upwards their dust, which tints the smoke of a dark colour, and, falling around the volcano, constitutes one of the forms of "volcanic ash," the chemical composition of which represents that of all the rocks triturated *plus* the saline substances condensed from the smoke. If one walks across this ash when damp, one may notice the immediate plating of their boot-nails with copper, showing the abundance of the chloride of that metal.

H. J. JOHNSTON-LAVIS

THE ADELAIDE BOTANIC GARDEN AND GOVERNMENT PLANTATION

THE report of Dr. Schomburgk on the progress and condition of the Botanic Garden and Government Plantation, Adelaide, during the year 1885 has just reached us. Speaking first of the rainfall, Dr. Schomburgk says that the year was one of the driest and most ungenial that he ever had to contend with, the rainfall being no more than 15·887 inches, which was 2·851 inches less than the fall of 1884, and 5·272 below the average rainfall during the previous forty years. During September, October, November, December, and January no more than 3 inches of rain fell, and the heat during these months was abnormally great. The drought and heat combined had an injurious effect upon the vegetation, especially upon many of the trees and shrubs in the Botanic Garden, natives of cooler countries; the losses sustained, however, were not so great as was expected, owing to an abundant supply of water. On the other hand, in May and June severe frosts were experienced, so that tropical and sub-tropical plants and shrubs suffered greatly.

On the question of the introduction and acclimatisation of new economic plants, Dr. Schomburgk records his experience with many that have been widely distributed through the agency of the Royal Gardens, Kew, and have become known and established in other colonies as well as in India, such, for instance, as the Kumara (*Ipomœa chrysorrhiza*), the tubers of which form an article of food in New Zealand. Dr. Schomburgk says he believes that the plant will grow well in the gullies, because the climate there is cooler and moister than on the plains, and to some extent approaches that of New Zealand. The Gingelly oil plant (*Sesamum indicum*) is also reported upon favourably. The seeds were sown in drills in the open ground in October, and came up in about fourteen days. Considering that neither the dry spring nor the summer heat affected the plants, there seems no doubt that the species can be successfully cultivated in South Australia. The plant is an annual, and is very largely grown in warm countries for the sake of the sweet limpid oil now so much used for mixing with olive oil.

Under the head of *Rhopala* sp. an announcement is made of the receipt from Kew of a parcel of seeds of a tree belonging to the above-named genus, a native of Columbia, with the following extract from a letter of Mr. W. T. Thiselton Dyer:—"The Rhopala is a small contorted tree growing to about twenty feet in height. It is remarkable for being absolutely indestructible by fire, in large districts where the dry pastures and bush are burnt twice a year. Its resistance to fire enables it to exist to the exclusion of all other trees and bushes as a perfect natural plantation. The periodical burning destroys everything except this tree. The resemblance to a plantation is moreover enhanced by the circumstance that the trees never form thickets, and they are thickly and almost systematically dispersed over the land. The tree delights in the most sterile soils, but always of a stony or shingly character. Sometimes it grows in places so barren that even grass cannot exist. This suggests the idea that it may be turned to account in sterile districts within the tropics." Dr. Schomburgk expresses some doubt whether the plant will thrive out of doors with them, but thinks it may do well in the Northern Territory.

The Herbarium and Museum have both been considerably enriched by additional specimens during the year, so that the utility and efficiency of the whole establishment are thoroughly maintained.

THE AMERICAN ASSOCIATION

FROM the report in *Science* of the Buffalo meeting of the American Association we condense the following brief summary:—

Prof. Gibbs's masterly address, in the Section of Mathematics and Astronomy, upon the subject of "Multiple Algebra," was too long and of too technical a nature for presentation in full to our readers. His opening remarks were as follows:—

"It has been said that 'the human mind has never invented a labour-saving machine equal to algebra.' If this be true, it is but natural and proper that an age like our own, characterised

by the multiplication of labour-saving machinery, should be distinguished by an unexampled development of this most refined and most beautiful of machines. That such has been the case, no one will question. The improvement has been in every part. Even to enumerate the principal lines of advance would be a task for any one—for me, an impossibility. But if we should ask in what direction the advance has been made, what is to characterise the development of algebra in our day, we may, I think, point to that broadening of its fields and methods which gives us 'multiple algebra.'"

The speaker then gave a critical historical review of the different contributions of Hamilton, Möbius, Grassmann, Saint-Venant, Cauchy, Cayley, Hankel, the Peirces, father and son, and Sylvester, to these new methods of mathematical analysis, showing the additions and developments made by each to the various subjects.

In the second part of the paper Prof. Gibbs criticised the methods of some modern writers on these subjects, showing how they failed to grasp the full significance and bearings of the matters they were dealing with, being too much hampered by the old ideas and methods of simple algebra.

In the third part of his paper Prof. Gibbs directed attention more critically to multiple algebra itself, and inquired into its essential character and its most important principles.

Then followed a long discussion of the fundamental conceptions and methods of modern mathematics, which nothing but publication in full could render intelligible, and that only to mathematicians.

The fourth part of the paper was devoted to consideration of some of the applications of multiple algebra. From this we quote the following:—"First of all, geometry, and the geometrical sciences which treat of things having position in space,—kinematics, mechanics, astronomy, crystallography,—seem to demand a method of this kind, for position in space is essentially a multiple quantity, and can only be represented by simple quantities in an arbitrary and cumbersome manner. For this reason, and because our spatial intuitions are more developed than those of any other class of mathematical relations, these subjects are especially adapted to introduce the student to the methods of multiple algebra. Here Nature herself takes us by the hand, and leads us along by easy steps, as a mother teaches her child to walk. In the contemplation of these subjects Möbius, Hamilton, and Grassmann formed their algebras, although the philosophical mind of the last was not satisfied until he had produced a system unfettered by any spatial relations. It is probably in connection with these subjects that the notions of multiple algebra are most widely disseminated. Maxwell's 'Treatise on Electricity and Magnetism' has done so much to familiarise students of physics with quaternion notations, that it seems impossible that this subject should ever again be entirely divorced from the methods of multiple algebra. I wish that I could say as much of astronomy. It is, I think, to be regretted that the oldest of the scientific applications of mathematics, the most dignified, the most conservative, should keep so far aloof from the youngest of mathematical methods; and standing, as I do to-day, by some chance, among astronomers, although not of the guild, I cannot but endeavour to improve the opportunity by expressing my conviction of the advantages which astronomers might gain by employing some of the methods of multiple algebra. A very few of the fundamental notions of a vector analysis, the addition of vectors and what quaternionists would call 'the scalar part and the vector part of the product of two vectors' (which may be defined without the definition of the quaternion)—these three notions, with some four fundamental properties relating to them, are sufficient to reduce enormously the labour of mastering such subjects as the elementary theory of orbits, the determination of an orbit from three observations, the differential equations which are used in determining the best orbit from an indefinite number of observations by the method of least squares, or those which give the perturbations when the elements are treated as variable. In all these subjects the analytical work is greatly simplified, and it is far easier to get the best form for numerical calculation than in the use of the ordinary analysis."

Then followed illustrations of the various methods of applying multiple algebra to different classes of problems.

Prof. Brackett's address on "The Seat of the Electromotive Force" was essentially a *résumé* of the history of the investigations to find the source of the current in galvanic batteries. No attempt was made to settle the question, which has been so long a bone of contention.

In his address to the Section of Biology, Dr. H. P. Bowditch, of Boston, concluded that investigations into the chemical changes, the heat production, and the fatigue of active nerves, all tend to results more favourable to a kinetic than to a discharging theory of nerve action.

In the Section of Anthropology a novel and ingenious method of getting an insight into the unconscious mechanism of authorship was described by Mr. T. C. Mendenhall, under the title "Characteristic Curves of Composition." The method consists in counting the number of words of each length, from one letter to fourteen, fifteen, or as long as were found, and plotting the result on a curve, in which the abscissæ represented the number of letters in the word, and the ordinates the number of words per thousand of each length. It was shown that while the curve resulting from each thousand words was not entirely regular, that resulting from five thousand was much more regular, and that from ten thousand almost entirely so. The inference from this was, that the phenomenon which the curve represented was a regular one, and that it was an expression of the peculiar vocabulary of the author. Moreover, by comparing the respective curves, one would be able to judge whether two works were written by the same author, and perhaps even decide the controversy whether Bacon wrote Shakespeare. Mr. Mendenhall's method was to count a thousand words at a sitting, and then turn to another part of the book. One soon acquired the art of counting at a glance the number of letters in each word, and, with an assistant to record the result, one thousand words could be counted in a half-hour. Curves derived from Dickens ("Oliver Twist") and Thackeray ("Vanity Fair") were remarkably similar, thus suggesting that the subject-matter might cause the peculiarity of the curve, while those from John Stuart Mill ("Political Economy" and "Essay on Liberty") differed from them in having more long words and fewer short ones, though words of two letters (prepositions mainly) were most abundant in Mill. The average length of the novelists' words was 4·38, and that of the philosopher 4·8.

The geological interest of the meeting at Buffalo naturally centred in the excursion to and discussion of the Falls and gorge of Niagara. Dr. Pohlman, of Buffalo, described the district to be visited on Saturday, and called particular attention to the occurrence of drift-filled antecedent channels on the line selected by the post-Glacial overflow of Lake Erie, which would gradually diminish the amount of rock-cutting required in the excavation of the present gorge, and thus reduce the time since the overflow began. The geological members of the excursion party therefore gave close attention to these matters, and, as a whole, regarded the heavy drift between the sloping rocky banks at the whirlpool, and the wide, open valley, with its plentiful drift at St. David's, as sufficient evidence of an old buried channel connecting these points, and probably heading up above the whirlpool towards the bridges. But there seemed no sufficient reason for any confident belief in a branching old valley from the whirlpool towards the Lewiston bluffs: in making this lower part of the gorge there must have been a long period of deep rock-cutting between the first leap of the Falls over the bluff and the time of their discovering the old drift-channel and the whirlpool. The estimate of the age of the Falls was presented by Messrs. Woodward and Gilbert, of the Geological Survey, and their remarks greatly interested a large audience that had gathered on the announcement of the discussion. Mr. Woodward had just completed a survey of the Horseshoe Falls, and by comparing his results with those of the State Survey in 1842, and of the Lake Survey in 1875, he found an average recession for the whole face of the Fall of about $2\frac{4}{10}$ feet per annum; but as the central parts of the curve, where the water is deepest, has retreated from 200 to 275 feet in the eleven years since 1875, an average retreat of 5 feet per annum does not seem at all improbable. Mr. Gilbert then discussed the beginning of the Falls as controlled by the drainage of the lakes. When the retreating ice-sheet stood so as to obstruct the St. Lawrence and Mohawk drainage channels to the east, a broad sheet of water, representing a confluent of Erie and Ontario, stood at a high level over the present Niagara limestone plateau, and probably drained south-westward to the Ohio. When further melting opened the Mohawk Channel, the great double lake fell to a lower level, and was separated into its two members, Ontario sinking to the level of its outlet at Rome in Central New York, but Erie being held higher by the rim of the Niagara plateau. This was the birth of the river and the Falls, and since then they have been at work on the gorge. The age of the falls thus carries us back to a tolerably definite point in

the decline of the Glacial period. On the supposition of a uniform rate of recession, the age of the Falls equals the length of the gorge divided by the annual recession; but the rate has been undoubtedly varied by changes in a variety of conditions, which must be allowed for. As thus qualified, Mr. Gilbert gave it as his conclusion that the maximum length of time since the birth of the Falls by the separation of the lakes is only 7000 years, and that even this small measure may need significant reduction.

In the Section of Chemistry, H. C. Bolton, of the Committee on Indexing Chemical Literature, after presenting their report showing the large amount of valuable work which was being done, read a paper on the confusion which exists in the abbreviations employed in chemical bibliography, and the desirability of uniformity in designations of scientific periodicals.

C. F. Mabery's paper "On the Products of the Cowles Electric Furnace," was of particular interest, and attracted much attention. He stated that the past year had been devoted more especially to the development of an increased commercial efficiency of the furnace, so that now 300 horse-power could by means of a large dynamo, be applied with greater economy in the results; and by coating the charcoal employed in the furnace with lime, by soaking it in lime-water, the production of graphite was largely avoided, and a marked improvement in the working of the furnace introduced. The results—although, as compared to what would eventually be accomplished by electric smelting, they may seem crude—have reached a stage where their commercial success can be demonstrated. It was also found that when the electrodes entered the mixture in a slanting position the product was increased. They are now also moved in and out with advantage, being gradually withdrawn as the resistance falls. Prof. Mabery replied to the criticisms of Hehner of Berlin, Siemens, and others, that no new principle was involved, showing that the Cowles furnace is quite different from all hitherto constructed, and the only one of practical application by which a dynamo of 300 horse-power could be used, as by means of a resistance-box and the arrangement of the furnace, the sudden breaking of the current is prevented from burning out the dynamo. The presence of copper for the reduction of aluminium was shown to be unnecessary; and, by complete exclusion of air from the furnace, buttons of the metal were easily obtained. A product which has attracted considerable attention during the past year is obtained by reducing aluminium in presence of iron. A cast iron is formed containing sometimes as much as 10 per cent. of aluminium, and this product is used to facilitate the working of crude iron, and to introduce into the various grades a small percentage of aluminium. In the reduction of aluminium in the presence of copper a yellow product is frequently taken from the furnace, which is composed of metallic aluminium to the extent of one-half or three-fourths, the balance being silicon and copper. It is also formed in the absence of copper, and then contains a higher percentage of aluminium, and always contains nitrogen. It has a resinous lustre, and decomposes water at 100°.

In the Section of Physics, Prof. T. C. Mendenhall prefaced his paper on "Electric Thermometry" by saying that the strictures upon the mercurial thermometer should not be carried too far. It has been of great value, though it may now fail to meet new demands. Electric thermometry is receiving especial investigation at the Signal Office, particularly from the meteorological stand-point, with some promising results. Prof. Mendenhall reported the progress which had been made in the study of atmospheric electricity during the past year. It is not time to begin to think of the origin of atmospheric electricity. The problem is its distribution and the relation, if there be any, to weather changes. Some very interesting results have been reached. In ordinary weather the electrical condition is undergoing constant and rather wide variations, which are very local, as two collectors only a few feet apart may give curves differing considerably, though similar in their wider variations. When an electrical storm occurs, the curves over a wide area may be similar in general outline. Prof. Mendenhall also noted a phenomenon entirely new to him; namely, that resistance-coils, after a current it passed through them for some time, upon short-circuiting will yield a reverse current for hours. This phenomenon can no doubt be classed under the general head of polarisation, yet by simple polarisation it would be difficult to account for persistence of current. This makes caution necessary in the use of resistance-coils, in order that any effects of this kind may be carefully noted. In one instance the apparent resistance of a coil was found to increase fourfold when the current was reversed.

A paper by Prof. Abbe created some discussion. The point of the paper was that, as the force of gravity varied from the equator to the poles, 30 inches of mercury in the barometer indicated a less gaseous pressure, and consequently less density of the atmosphere, at the equator than 30 inches at the poles, and hence a correction for latitude should be introduced in allowing for refraction. He showed that, for the difference of latitude of Pulkowa and Washington, it would make 0″·1 difference in the refraction at 45° of zenith-distance, and might be sufficient partly to account for differences in systems of star declinations which depended upon observations at great zenith-distances.

In the Section of Biology, the paper of Messrs. J. M. Coulter and J. N. Rose, giving a synopsis of the North American pines, based on leaf-structure, was of especial value from a systematic stand-point, from the fact that any species in this somewhat difficult group can at once be distinguished by the peculiarities of its minute leaf-structure; and the results of the author's observations are shown to be worthy of attention from the fact that a classification based on these characters is, in its broader features, closely like that of the late Dr. Engelmann, which, as is well known, took into consideration the whole tree.

The relations of germs to disease naturally occupied a prominent place in the proceedings of the Section, and the presence of over half a dozen investigators in this line made the discussions interesting. Dr. D. E. Salmon read two papers bearing on the causes of immunity from a second attack of germ diseases. There are three possible explanations:—(1) Something is deposited in the body during the attack which is unfavourable to the germ; (2) something has been withdrawn which is necessary to its development; (3) the tissues have acquired such a tolerance for the germ or for an accompanying poison that they are no longer affected by it. Dr. Salmon favoured the last view, and gave details of a large number of experiments to substantiate his opinion. He said that Metchinkoff's phagocyte theory was not wholly satisfactory, and that large doses of the germs were more powerful than small ones. He attributed their action to a poison which was a result of their growth, and thought that a large dose had a greater effect because the poison benumbed or killed the cells, thus giving the Bacteria a better chance to grow and to thus produce more poison.

Dr. Joseph Jastrow gave an account of some physiological observations on ants, in which he was able, by simple but ingenious means, to study the rate of walk of these insects, and stated that his results, so far as they went, confirmed the opinions of others that the smaller the animal the more rapid the step, and also the more quickly fatigue was produced. Dr. Jastrow also had some observations on the dreams of the blind, taken mostly from persons who had lost the sense of sight before the age of five. In these cases the dreams were all in terms of hearing. In the case of Laura Bridgeman the dreams were apparently based on touch. In persons who become blind between five and seven, sight terms played an important part in dreams. The relation of these facts to the development of the sight-centres was pointed out.

PHOTOGRAPHIC DETERMINATIONS OF STELLAR POSITIONS[1]

IT has been suggested that a short account of my work upon stellar photographs for the attainment of accurate observations might be acceptable to the astronomical section. My intention had been to attend this meeting as a listener and learner only, but I comply with the suggestion the more readily, since, by a notable coincidence, I spoke upon the same subject in this place just twenty years ago this week. It is true that my communication then was only an oral one, and never reduced to writing, for the successful establishment of the Atlantic cable, of which I had received notice that day, called me away suddenly, before the time fixed for the regular presentation; but an elaborate written memoir upon the subject had been presented to the National Academy, ten days previous, at Northampton.

The early history of celestial photography is demonstrably and exclusively American; and its use as a method of delicate quantitative research is very markedly so. Without entering upon

[1] Paper read at the Buffalo Meeting of the American Association for the Advancement of Science, August 20, 1886.

the historical data, which are of easy access to every investigator, I may mention that No. 77 of the *Astronomical Journal* contained nineteen photographic impressions of as many different phases of the solar eclipse of 1854, May 26—the moment of each impression being given to the nearest tenth of a second. These were taken at West Point, under the direction of Prof. Bartlett, of the U.S. Military Academy, and form a part of his memoir, in which he also gives the distances between the cusps, as measured by himself with the micrometer in the telescope. Ten years later, in 1864, Mr. Rutherfurd constructed the $11\frac{1}{4}$-inch photographic object-glass which has acquired so conspicuous a place in astronomical history; and with this, in addition to its other achievements, he obtained sharp photographic stellar images, with a definition previously unknown, taking for the first time distinct impressions of stars invisible to the naked eye, in fact to the $8\frac{3}{4}$ magnitude for white stars.

After constructing a micrometer of great delicacy for the measurement of these plates, he measured with this the relative distances and position-angles of the stars which they contained. And in the spring of 1866 he kindly placed in my hands the results thus derived from three plates of the Pleiades, each containing two impressions, taken on the evening of March 10. One of these plates contained forty stars. Bessel's memoir upon the Pleiades, published in 1844, gave the relative positions of fifty-four stars, measured with the Königsberg heliometer, during the years 1829 to 1841. Six of these fifty-four do not belong within the limits of the plate (which contains about one square degree), and ten of them are too faint for the photographic record, so that sixteen of Bessel's list are wanting; but, on the other hand, there are two additional ones, not observed by him.

From this fact alone it may be perceived that among the great benefits which astronomy may be justified in expecting from celestial photography, the accurate determination of magnitudes does not find place. The chemical action of the stellar light upon the film is so dependent upon the character of that light that, in the absence of a correct knowledge of its composition, we are very easily deceived regarding the amount. Thus one of Bessel's stars which was not recorded upon any of Mr. Rutherfurd's plates is estimated by Argelander as of the magnitude 8·0, and by Wolf as $7\frac{3}{4}$, while five are distinctly recorded which Argelander calls $8\frac{1}{2}$ or less, and eight which Wolf so estimates. The spectroscope would doubtless show a deficiency of the more refrangible rays in the light of the former, and a preponderance of the same in that of the latter.

This series of measurements by Mr. Rutherfurd, together with the computations to which the results were submitted, constitute, if I am not mistaken, the first application of the photographic method to exact astronomical determinations. And the investigation necessarily demanded especial care, both for guarding the numerical results against sources of unsuspected error and for fixing the limits within which known theoretical errors would remain unappreciable.

The importance of the successful application of a method so different from all previous ones, and so full of promise, and also the considerable time which would inevitably elapse before the memoir could be printed, led me at the same time to communicate to the *Astronomische Nachrichten*, at Altona, some of the resultant values. In a comparatively short note, written about the middle of August 1866, I gave for the ten most conspicuous stars of the Pleiades, after Alcyone, the corrections derived from one of the photographic plates of March 10, for the values, published by Bessel, for the position-angles and distances, from Alcyone in 1840, as likewise the average discordance found for a single measure.

In the next following year the Academy had not the means of printing its memoirs; and as in the meanwhile Mr. Rutherfurd had measured five more of the plates of the Pleiades previously taken, as well as six additional ones taken in the months of January and February 1867, these were also computed, and the results added to those from the first three plates in the memoir already written.

Various circumstances combined to delay the publication, chief among them being what seemed to me a manifest impropriety in printing the results derived from photographs and measurements made by Mr. Rutherfurd, and by his own methods, before some account of these methods should have been published by him. His communication on the subject had been made to the National Academy immediately previous to my own, but was not yet in such form as he desired for publication.

The result showed a very remarkable accordance with Bessel's determination for 1840, although the total amount of relative proper motion during the elapsed twenty-six years was comprised in the differences.

This memoir still remains in its original form, but unpublished; the results being deduced from twenty-four photographic impressions upon fourteen plates.

In the next year, 1868, I had the gratification of receiving from Mr. Rutherfurd the results of his measurements of thirty-two stars of the cluster Præsepe, derived from eleven impressions. These were computed in the same way that those of the Pleiades had been, and an analogous memoir upon this cluster was prepared for the National Academy.

Before leaving the country, early in 1870, I gave these two memoirs to Mr. Rutherfurd, with the request that he would send them to the printer, at the same time with his own paper, already mentioned, but not before then. The condition of his health prevented him from attending to the matter for some time, and in the interval he arrived at the unpleasant discovery that the screw of his micrometer had suffered from wear, and to an extent which led him to fear a want of that accuracy of which the method is susceptible, and which he hoped to see demonstrated by its very first applications.

Notwithstanding this possible blemish, it seems to me that the results ought to be now made public in their original form, after due mention of the circumstances; and it is among my hopes to be able soon to publish these two memoirs from the original manuscript of so many years ago.

The method was received with manifest distrust and disregard abroad; and, as was but natural for so essential a deviation from former methods, very many grounds of criticism and objection were brought up. One of the principal of these was the possible distortion of the collodion film, after receiving the impressions and before the measurements; but Mr. Rutherfurd speedily disposed of this point, at least so far as the albumenised plates are concerned; and, moreover, the combination of measurements of the same stars derived from various plates will at once make manifest the degree of confidence to which the several values and their wear are respectively entitled.

A far more serious obstacle to accuracy is presented by the difficulty of obtaining absolutely round images. Irregularity of form in the dots formed by the stellar impressions is almost incompatible with precision of measurement; and, as the time of exposure must often be long, the chief problem was, not so much to obtain the images as to insure uniformity of motion in the telescope during the period of exposure. Not that the photographic processes were not troublesome enough before the introduction of the dry-plate processes, for very great care and numerous precautions were often necessary to prevent the plates from drying too fast; but far the greatest difficulty consisted in obtaining sufficient precision in the clockwork and equatorial motion of the telescope.

It may easily be imagined how great was my desire, when leaving home for South America, to extend this new method of observation to the southern hemisphere. But the obstacles encountered in the endeavour cannot be easily imagined. Upon these I will not enlarge here further than by saying that in Cordova also the attainment of circular dots for the star images offered incomparably the greatest of all the difficulties of a practical character. The time of exposure was limited by the maximum size allowable for the large stars, and, previous to 1878, also by the drying of the plate, although exposures of twenty minutes were not unusual. Nevertheless, by dint of specially constructed governors and regulators, and by ceaseless attention, we did succeed in obtaining impressions which, to the unaided eye, appear absolutely round.

This necessity of long-continued and minute uniformity in the motion of the telescope is, of course, largely diminished by the employment of instruments of large aperture, inasmuch as the necessary time of exposure is diminished in the same ratio in which the amount of light is increased. It is yet further and most notably diminished by the manifold greater sensitiveness of the dry gelatine plates. But notwithstanding all this, the attainment of round images, while almost indispensable for giving to stellar photography that increased accuracy to which it may lay claim as a means of research in practical astronomy, still demands especial care and precaution.

The Argentine Government cordially afforded every assistance which I deemed it proper to ask for these investigations. And although the chief energies of the Cordova Observatory

were absorbed by those investigations for which the institution was established, I had the satisfaction of obtaining a sufficient number of stellar photographs to occupy not only my own lifetime, but many more, in their measurement and proper computation.

We photographed no northern stars there except the Pleiades and the Præsepe. Of the Pleiades I brought home sixteen plates, with two impressions of the whole group upon each, made in five different years, from 1872 to 1882, inclusive. Although the centre of the cluster never attains a greater altitude at Cordova than 34° 50′, some of the plates contain seventy stars. All but one of Bessel's stars are there, which belong within the limits of the field, the missing one being of the magnitude 9½, and there are yet other stars of the magnitudes 10, 10½, and 11. Of the Præsepe there are five plates, and with a correspondingly increased number of stars.

About seventy southern clusters have been repeatedly photographed at Cordova, comprising all those of the southern hemisphere which seemed important, also somewhat more than a hundred double stars, being a sufficient number to serve as a good test of the method. The total number of photographs now on hand is somewhat less than 1300, only few having been preserved in which the images were not circular.

Especial attention, however, was given for many years to taking frequent impressions, at the proper seasons, of four stars selected, on account of their large proper motion, as likely to manifest appreciable annual parallaxes. The refined and elaborate observations of Drs. Gill and Elkin, at Cape Town, have been made, computed, and published, while the Cordova photographs have lain untouched in their boxes. There is but one of my four stars, β Hydri, which is not included in their list. Still, it will be a matter of much interest to apply the photographic investigation to the same problem, even if for no other purpose than a comparison of the results of the two methods.

I am convinced that the Cordova plates contain a large number of stars as faint as the eleventh magnitude of Argelander's scale, and believe that these are much the earliest photographs of stars fainter than Mr. Rutherfurd's of 1865 and 1866. There are several plates, covering about a degree square, which cannot contain less than 550 stars, and I believe that some of them contain a greater number. Such are those of the cluster Lac. 4375 and that near X Carinæ.

The region in the vicinity of η Carinæ, and that magnificent tract in Sagittarius which is too densely sown with stars to be considered merely a portion of the Milky Way, and yet too large and undefined to be regarded simply as a cluster, were both of them taken several times, during the years 1875–82, in series of overlapping photographs, each containing about a square degree, and recorded upon a glass surface of 9 by 12 centimetres. In their present form they are of course of small value for scientific use, inasmuch as the stars are too crowded for their configurations to be easily perceived; and although these two series form, in fact, maps of considerable regions in the sky, still the record is of a very perishable nature, and of small avail for use by astronomers until it shall have been translated into an enduring and numerical form by micrometric measurement.

In this connection I may say that one of the greatest of my present anxieties regarding the Cordova photographs arises from a discovery of the ease with which the collodion or gelatine film may become detached from the glass. The Argentine Government has assigned a moderate sum for the prosecution of the measurements, and with this some progress has already been made. It is but right to add that the full amount was given for which I asked. Still, it is now quite inadequate, in consequence of the unfortunate depreciation of the national currency; and, in the present financial crisis there, I cannot reasonably expect more. Yet this matter of prompt measurement appears to me at present much more important than it did while I was unaware of the facility with which the film can blister and peel.

In 1883, after Mr. Common's brilliant success in photographing nebulas with his great 3-foot reflector, he proposed to me a joint arrangement for photographing the whole heavens. My work at Cordova was so near its close that it was out of the question to undertake anything new; but the immense labour requisite for the measurement of the plates would, under any circumstances, have tended to deter me. It is an undertaking demanding the joint energy, application, and material resources of a large number of persons, if the results are to be made available for astronomical use; indeed, I see no other astronomical value in the unmeasured photographs than the possibility of confirming at some future epoch the existence of relative motion previously detected or made probable by some other investigation.

Since then the process of photographic charting is said to have been systematically undertaken by the Brothers Henry at Paris. I have seen none of their plates; but their sharpness is highly spoken of, and the work appears to be prosecuted with much skill and very sensitive plates. There can of course be no question as to the value of any permanent record whatsoever, corresponding to a known date; yet I cannot feel that any essential advance is likely to be made in this way until the photographic record shall have been brought within the range of numerical expression.

The measurements of the Cordova photographs, thus far completed, are those of the double stars, the four stars with large proper motion, of the Pleiades, of the Præsepe, and of the clusters Lac. 4375 and κ Crucis. The corresponding computations have been made, as yet, only for a portion of the Pleiades impressions, but I am hopeful of completing all these at a comparatively early date. We shall then be able not only to compare the results with Bessel's of forty-five years ago, but to test the deduced values of the proper motions by means of the photographic determinations of 1865 and 1866. Meanwhile, the valuable memoir of Wolf has been published, giving closely approximate positions for 571 stars of the group, and Dr. Elkin has recently been executing at New Haven a heliometric triangulation of the principal stars. Our photographic results will have to be confronted with his delicate heliometric ones; and, should they bear this test with tolerable success, it will be all that can reasonably be desired.

B. A. GOULD

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

PROF. W. GRYLLS ADAMS, F.R.S., will deliver, at King's College, London, a course of lectures on Electricity and Magnetism and their applications to Electric Lighting, Transmission of Power, &c., during the academical year 1886–87. A course of practical work in Electrical Testing and Measurement with especial reference to Electrical Engineering will also be carried on under his direction in the Wheatstone Laboratory. In the Wheatstone Laboratory, which is open daily for research from 1 to 4, except on Saturdays, there are special courses of practical work for students preparing for the Science Examinations of the University of London.

IT is purposed to celebrate, in a befitting manner, from November 6 to 8 next, the 250th anniversary of the founding of Harvard University, Cambridge, Massachusetts. The University was established on November 7, 1636, by an Act of the Colonial Legislature, and was named after John Harvard, who was a liberal benefactor of the new institution. Harvard is the oldest University in North America. The southern portion of the Continent possesses one many years older—the University of St. Mark, at Lima, founded in 1551 by the Emperor Charles V.

SCIENTIFIC SERIALS

Bulletin de l'Académie Royale de Belgique, July.—Modern kinetics and the dynamism of the future, by G. A. Hirn. The author replies to the arguments urged by M. Clausius against his view of the kinetic theory in its application to the resistance of gases. He continues to treat the question in connection with his peculiar spiritualistic opinions, and endeavours to overthrow the theory now generally accepted by physicists, because of the disastrous consequences which he supposes it would have on the progress of mankind.—On a class of conjugated polynomes, by J. Deruyts. This memoir, which is a further development of the author's previous researches, deals more especially with the important functions presented by certain polynomes in the approximate calculation of definite integrals.—On the distribution of the regenerate nerves, by C. Vauclair. In this paper the author deals with the peripheric distribution of the regenerate nerves compared with that of the primitive nervous system.—Essay on the origin of the Fraunhofer rays in relation to the

constitution of the sun, by Ch. Fievez. Given the high temperature, chemical composition, and slight mean density of the sun, its chemical elements cannot exist in the solid or fluid state, or even to any large extent in the condition of highly compressed vapours. Assuming, further, with most physicists, that the sun consists of a gaseous mass whose temperature increases from the circumference towards the centre, it is argued that the solar spectrum must be formed by the superposition of all the radiations of the chemical elements present in the sun. The luminous part of the spectrum would thus be constituted by the radiations of like vibratory period, and Fraunhofer lines by the radiations of unlike vibratory periods. From this it would follow that a chemical element might exist in the sun without being revealed by a dark line in the solar spectrum.

Schriften der Physikalische-Ökonomischen Gesellschaft zu Königsberg i/Pr., 1885.—Herr Fritsch here gives the result of a study of certain gaps in the pith of Coniferæ, discovered by Prof. Caspary some years ago. In its middle course the pith of a year's growth consists of elongated parenchyma, but at the end of the growth it presents cubic or egg-shaped cells in loose union. Those gaps the author finds in species of the genera Abies, Picea, and Larix, and in *Cedrus Deodara*. The last-named differs from the others in not having a partition of cross-lying cells through the pith, above the gaps. All Coniferæ with persistent bud scales have this, and some Coniferæ (*Tsuga canadensis* and *Torreya nucifera*) have it, and are without the gaps. Finally, the Junipereæ, Podocarpeæ, Taxineæ, and Pinus have neither. The gaps seem to arise through stretching of the wood-cells, and their size depends on the age and moisture of the stem and branches.—Herr Franz writes on the magnetism observed at the end of long iron well-tubes (200 and 250 m.) at Königsberg, and of some railway lines. The attractive force was proportional to the distance (not its square), the magnetism being pretty equally distributed over a line several metres long. In one well, the horizontal component at 1 metre distance was as much as fifteen times that of the earth's magnetism.—Herr Klien describes experiments in plant cultivation by the water-method (specifying the substances given in solution and their amount), and points out its advantage in study of the action of poisons, such as the sulphocyanite of ammonium occurring in ammonia superphosphate from gas manufacture, and spoiling that product for manure purposes.—A paper by Herr Scharlop appears to throw light on the production of some prehistoric urns in Prussia, from a mode of manufacture which has lately died out.—Dr. Tischler discusses the representations of weapons and costumes on old bronzes of the Hallstadt-Italian period.

SOCIETIES AND ACADEMIES

London

Entomological Society, September 1.—Robert McLachlan, F.R.S., President, in the chair.—The following gentlemen were elected Fellows:—The Rev. Prof. Dickson, D.D., and Messrs. P. Cowell, A. O. Walker, and Lyddon Surrage.—The President remarked with regard to the gnats from the Kent Waterworks, exhibited at the last meeting, that Prof. Westwood had since informed Mr. Douglas that they were only *Culex pipiens*.—Mr. Slater exhibited certain parasites found on the body of a larva of *Smerinthus tiliæ*, which Mr. Waterhouse believed to be *Uropoda vegetans*, a species of *Acari*.—Mr. W. Warren exhibited *Eupithecia fraxinata*, *E. innotata*, a variety of *E. satyrata*, a *Gelechia* caught in Wicken Fen twenty years ago by Mr. Bond, and believed to be a new species, *G. fumatella*, *G. vilella*, *Lithocolletis scabiosella*, and *Catoptria parvulana*. He also exhibited larvæ of *Gelechia vilella*.—Mr. South exhibited specimens of *Dicrorampha distinctana*, and stated that he considered it to be merely a local form of *D. consortana*, from which, in the larval stage, it could not be separated.—Mr. Stevens exhibited a living specimen of *Clerus formicarius*, recently found under the bark of an ash-tree in Arundel Park.—Mr. Billups exhibited *Chrysis succincta*, Linn., taken by sweeping at Chobham on July 28 last; he also exhibited *Microphysa elegantula*, taken at Broadstairs in August last.—The Rev. W. W. Fowler exhibited, on behalf of Mr. Theodore Wood, a larva of *Langelandia anophthalma*, a species new t[illegible] Britain.—Mr. H. Goss exhibited specimens of *Oxygastra Cu*[illegible] recently taken near Christchurch, Hants. He stated tha[illegible]d met with the species in the same locality in 1878, but n[illegible]r seen it anywhere else in the United Kingdom, nor was he aware of any recent record of its capture. Mr. McLachlan observed that the species was taken many years ago in Dorsetshire by the late Mr. Dale, but that he knew of no recent captures except those recorded by Mr. Goss. He also made some remarks as to the distribution of the species on the continent of Europe.—Mr. McLachlan exhibited a specimen of *Dilar meridionalis* taken by him in July last in the Pyrenees, also about 150 examples of the genus *Chrysopa* from the same district. Amongst them were *C. vulgaris*, *perla*, *Walkeri*, *viridana*, *tenella*, *prasina*, *flava*, *septempunctata*, *flavifrons*, and others not yet fully identified. He also exhibited a few Coleoptera from the same district, and remarked on the extraordinary abundance of a pretty Lamellicorn, which was so common as to give the meadows the appearance of being studded with multitudes of brilliant blue flowers.—Mr. C. O. Waterhouse called attention to the numerous reports which had lately appeared in the newspapers of the supposed occurrence of the Hessian Fly (*Cecidomyia destructor*) in Britain, and inquired whether any communication on the subject had reached the Society. The Rev. W. W. Fowler stated that he had been in communication with Miss Ormerod on the subject, and that she had informed him that neither the imago nor larva of the species had been seen, and that the identity of the species rested on the supposed discovery of the pupa.—Mr. A. H. Swinton communicated a paper entitled "The Dances of the Golden Swift." In this paper the author expressed an opinion that the peculiar oscillating flight of the male of this and allied species had the effect of distributing certain odours for the purpose of attracting the females.

Paris

Academy of Sciences, September 27.—M. Émile Blanchard in the chair.—Researches on the sugars, by M. Berthelot. The results are given of recent studies of some new principles obtained from the association of sugars with themselves, not by a stable combination of the class of saccharose substances, but by a combination easily dissolved, analogous to that of the hydrates and alcoholates. The facts observed illustrate the difficulties so often met with in the preparation of the double salts. They supply a fresh proof of the special part played by the dissolvents in the extraction of immediate principles, for, according as water or alcohol is employed, melitose or raffinose may be obtained.—Conditions determining the rapidity of images in chronophotography, by M. Marey. By the process here described, which is based on M. Chevreul's method of obtaining a perfectly black ground, the author is enabled to reduce the time of pose for each image to the two-thousandth of a second, and hopes by further improved dispositions to reduce it still more. The new photographs show that this reduction of time greatly increases the delicacy of the images obtained by this process of chronophotography.—Kinematic analysis of the locomotion of a horse, by M. Marey. In this paper are described and illustrated the movements of the fore-leg in the step, trot, and gallop. The tendency to economy of labour displayed in various degrees in the movements of all "animal machines" appears to attain the greatest perfection in the action of the horse, being, however, less evident in the trot and the gallop than in the slow pace.—Note on the removal of the Imperial Observatory of Rio de Janeiro to a new site, by M. Cruls. The new site, to which the Observatory will soon be removed, occupies about 40 hectares (100 acres) of the Imperial Fazenda of Santa Cruz, the usufruct of which is granted by the Emperor for this purpose. The new Observatory will stand on the same parallel, and about 2 metres to the west of the present establishment, and will be able to undertake observations both on atmospheric electricity and terrestrial magnetism much more successfully than was possible in its old home.—On the transformation of algebraic surfaces in themselves, and on a fundamental number in the theory of surfaces, by M. E. Picard. Having recently shown that surfaces capable of transformation in themselves by a birational substitution, including two arbitrary parameters, are of the genus zero or one, the author now examines the case of a single parameter, which he finds leads to totally different conclusions.—On a new method of determining the coefficient of expansion for solids, by M. Robert Weber. If a solid body be suspended like a pendulum, its oscillations will depend upon its form, its mass, and the distance of its molecules from the axis of rotation. At two varying temperatures this distance varies, whence results a change in the oscillations. Hence for a given body there is a determined relation between its temperature, u, the coefficient

of expansion, *a*, its dimensions, *d*, and time of oscillation, *t*. The value of *a* with these data may be calculated by the process here described, and in a future communication the author promises some values of coefficients of expansion determined by this method.—On the microscopic flora of sulphurous waters, by M. Louis Olivier. While prosecuting his researches on the reduction of the sulphates by living beings, the author has been led to the discovery of low organisms in sulphurous cold and thermal waters. These organisms are found to be very active at very high temperatures, thriving and multiplying themselves in the hot springs of Des Œufs (Cauterets), and elsewhere, at temperatures of from 46° to 50° C. Carefully collected and transplanted to an extract of beef, they continued to propagate at 65°, and even nearly to 70° C.—Influence of the organism of the guinea pig on the virulence of tuberculosis and scrofula, by M. S. Arloing. It results from several experiments that the virus of scrofula is not intensified by its presence for two generations in the guinea-pig. But the effect is different with true tuberculosis, which in its attenuated forms acquires by inoculation sufficient virulence to affect the rabbit, an animal otherwise so difficult to infect with this poison. —On the vascular system of the Echinidæ, by M. Henri Prouho. In reply to a statement recently made by M. Kœhler, the author shows by numerous quotations that, except on two points, their views are not in accord on the vascular system of these organisms.—The earthquake of August 27, 1886, in Greece, by M. Léon Vidal. The paper contains a detailed account of the disturbances in various parts of the mainland and adjacent archipelagoes, from which it appears that the phenomenon was due to a general cause situated somewhere to the south-west of the Island of Alphios, beyond the Strophades.—Remarks on a chart representing the Granitic and Cretaceous formations of the Spanish Pyrenees, and their disposition in a series of oblique ridges, by M. F. Schrader. On this map, drawn to a scale of 1 : 200,000, the author gives the results of his own surveys in a deep colour, marking off the districts which he has not yet visited, and for which he has utilised the works of Dufrénoy and Élie de Beaumont.—Explanation of the solar spots and faculæ, by M. J. Delauney. To explain these phenomena it is assumed that the sun consists of a very hot nucleus of metals in the fluid state wrapped in an atmosphere at a very high temperature and pressure, and formed almost entirely of hydrogen; further, that the nucleus contains in solution a large quantity of gas derived from the atmosphere; that the atmospheric pressure is least at the poles and at the equator, with a maximum at low latitudes on either side of the equator; lastly, that this atmosphere is subject to variations of pressure. The spots would then be caused by any atmospheric depression in any region of the solar surface, while the faculæ would correspond to an inverse phenomenon, the atmospheric hydrogen being absorbed or dissolved by the nucleus under the influence of high pressures. The spots would be the result of a cyclone, the faculæ of an anti-cyclone, the former being accompanied by a diminution of heat employed to transport the hydrogen from the interior of the sun to and even beyond the atmosphere, while the latter represent a liberation of heat resulting from the precipitation of the hydrogen absorbed in the solar mass.

STOCKHOLM

Academy of Sciences, September 15.—A refutation of the remarks of Dr. Hoppe on the new theory of unipolar induction, by Prof. E. Edlund.—On the Salmonidæ of the Swedish State Museum with reference to a work recently published on them, by Prof. F. A. Smith.—On the new parts (15 17) of "Algæ aquæ dulcis exsiccatæ quas distribuerunt," V. Wittrock and O. Nordstedt, exhibited and commented upon by Prof. V. Wittrock. Researches on the general Jupiter-perturbations of the asteroid Thetis, by Herr C. V. L. Charlier.—Some new developments of the elliptic functions, by Prof. Hugo Gyldén.—On the habits of two Swedish species of the solitary wasps, by Prof. Chr. Aurivillius.—On a new nitro-naphthaline-sulphur-acid, by Prof. P. T. Cleve.—On glycolurite and acetylurea, by Prof. O. Widman.—On the products of oxidation of the ortho-nitrocumenolocryl-acid and its combinations, by the same.—New researches on the re-arrangements of the atoms in the propyl group, by the same.—On the curve of coincidence of the common algebraic differential equations of the first order, by Prof. C. F. E. Björling.—On the integration of the differential equations in the problem of the N-bodies, iii., by Prof. Dillner. —On the connection between the coefficients of expansion and the coefficients of elasticity at different degrees of temperature, by Prof. G. R. Dahlander.—On the determination of sulphur and haloods in organic combinations, by Dr. P. Klason.

BOOKS AND PAMPHLETS RECEIVED

"Lehrbuch der Vergleichenden Anatomie der Wirbelthiere," by Prof. Dr. R. Wiedersheim (Fischer, Jena).—"Edinburgh Astronomical Observations," vol. xv., by Prof. P. Smyth (Neill and Co.).—"Pictorial Arts of Japan," part 4, by Wm. Anderson (Low and Co.)—"A Treatise of Spherical Trigonometry," part 2, by W. J. McClelland and T. Preston (Macmillan and Co)—"Illustrated Hand-book of Victoria, Australia Ferres, Melbourne).—"Journal of Statistical Society," September (Stanford).—"Euclid Revised," Books i. and ii., by C. J. Nixon (Clarendon Press)—"Handbook of Zoology," 3rd edition, by Sir J. W. Dawson (Dawson, Montreal).—"Bulletin of the Amer. Mus. of Nat. Hist.," July 1886 (New York).—"British Fungi," vol. ii., by J. Stevenson (Blackwood).—"Challenger Reports, Zoology," vols. xv.-xvi. "Explosions in Coal-Mines," by W. N. and J. B. Atkinson (Longmans).—"Philosophische Studien," Dritter Band, 4 Heft, by W. Wundt (Engelmann, Leipzig).—"Proceedings of the Boston Society of Natural History," vol. xxiii. part 2 (Boston).—"Memoirs of the Boston Society of Natural History," vol. iii. No. 12, by W. K. Brooke; No. 13, by S. H. Scudder (Boston).—"Des Mesures absolues de la Chaleur rayonnante," by K. Angström (Upsal)—"Stonyhurst College Observatory: Results of Meteorological and Magnetical Observations, 1885," by Rev. S. J. Perry.—"Rules regarding Defects of Vision," by Sir J. Fayrer (Churchill).—"Ancient and Modern Methods of Arrow Release," by E. S. Morse (Essex Inst.).—"Results of Experiments at Rothamsted on the Growth of Barley," by Prof. J. H. Gilbert.—"Descriptive List of Native Plants of South Australia Recommended for Cultivation," by J. G. O. Tepper.

SCIENTIFIC WORTHIES

XXIV.—JOHN COUCH ADAMS

PROFESSOR J. C. ADAMS, whose portrait we this day present to our readers, entered St. John's College, Cambridge, in 1839. He soon gave promise of those great mathematical powers that have brought such renown to his University. He came out as Senior Wrangler in 1843, and the excellence of his answering is still a tradition at Cambridge.

By what seems to have been an inspiration of genius, he was guided after taking his degree to concentrate his talents on the solution of an astronomical problem of excessive interest but of corresponding difficulty. The planet Uranus had shown irregularities in its motion. The orbit differed from the elliptic path which an undisturbed planet would pursue, and the deviations could not be fully accounted for by the influences of the other known planets. The only explanation of the discrepancy which astronomers could be expected to favour lay in the supposition that there was some other still more remote planet yet unknown.

It was the search for this unknown planet which attracted the distinguished Senior Wrangler. We can imagine the delight with which a well-equipped mathematician would throw himself into the solution of such a problem. On it he was to concentrate the powers that had been cultivated during his University career.

The planet was to be sought for by the measured deviations of Uranus from its calculated positions. Those who have ever had occasion to study the planetary theory are well aware of the difficulty and the laborious intricacy of the subject. To most of us it has seemed a thorny and difficult problem when the planet is given to find the perturbations. What are we to say of the difficulty of the converse problem, Given the perturbations and find the planet! This was the problem which Adams faced, and which, to his imperishable fame, he succeeded in solving. The story of this discovery is familiar to all, and the controversies that arose have long since died away. To each of the joint discoverers, Leverrier and Adams, the gold medal of the Royal Astronomical Society was presented on February 11, 1848. In his address on the occasion, Sir John Herschel, speaking of the two astronomers, says:—

"M. Leverrier and Mr. Adams—names which as genius and destiny have joined them, I shall by no means put asunder; nor will they ever be pronounced apart so long as language shall celebrate the triumphs of Science in her sublimest walks. On the great discovery of Neptune, which may be said to have surpassed, by intelligible and legitimate means, the wildest pretensions of clairvoyance, it would now be quite superfluous for me to dilate. That glorious event and the steps which led to it, and the various lights in which it has been placed, are already familiar to every one having the least tincture of science. . . . I will only add that as there is not nor henceforth ever can be the slightest rivalry on the subject between these two illustrious men—as they have met as brothers, and as such will, I trust, ever regard each other—we have made, we could make, no distinction between them on this occasion. May they both long adorn and augment our science, and add to their own fame, already so high and so pure, by fresh achievements."

The discovery of Neptune was a brilliant inauguration of the astronomical career of Adams. We cannot here enter into a detailed account of his numerous labours. There is an admirable account given of them up to the year 1866 in the address of Mr. De la Rue to the Royal Astronomical Society, when Adams was again the recipient of a gold medal. We find that he has worked at and written upon the theory of the motions of Biela's comet; he made important corrections to the theory of Saturn; he made an elaborate investigation of the mass of Uranus, to which he was naturally attracted from its importance in the theory of Neptune; he has improved the methods of computing the orbits of double stars: but next to the discovery of Neptune the fame of Adams mainly rests on his researches on the moon and on the theory of the November meteors. To each of these subjects we must devote some attention.

In the *Phil. Trans.*, vol. cxliii. part iii. p. 397, his paper was published "on the secular variation of the moon's mean motion." This memoir originated a long controversy, in which the ablest mathematicians have participated.

The "secular acceleration of the moon's mean motion" is the phrase which denotes a gradual but excessively slow diminution in the moon's periodic time. Although the amount of this diminution is very minute, yet the fact that it always tended in the same direction rendered the amount accumulative, so as to become very perceptible in the succession of ages. The explanation of the acceleration formed a problem on which the great mathematicians at the close of the last century exercised their powers, and at length the explanation was given by Laplace. He found that, when the analytical expression for the moon's mean motion was developed, it contained certain terms depending upon the eccentricity of the earth's orbit. This eccentricity varies in consequence of the planetary perturbations, and hence the changes of the moon's mean motion. Laplace calculated the amount, and deduced, or thought he had deduced, a correspondence between the observed value and the calculated value. The high authority of Laplace, and the brilliant success of his efforts to explain other perturbations in our system, led to an acquiescence in his results, and the great problem of the secular acceleration was believed to have been solved.

In Mr. Adams's paper he joined issue with Laplace. The question was fortunately one which did not involve any real element of uncertainty. It was a problem in mathematics, or rather dynamics—difficult no doubt, but not really open to any ambiguity. Prof. Adams showed that Laplace had only considered a part of the disturbing influence, and when the true amount was determined, it came out to be only about one-half that found by Laplace. So serious a charge received the careful consideration which it merited. Several leading mathematicians impugned the calculations of Adams, but he was able to vindicate his theory at every point, and finally the correctness of his calculations was verified in one manner by M. Delaunay, and in another by Prof. Cayley. The importance of this result is not to be estimated merely by its value as a correction to Laplace. The author of the "Mécanique Céleste," like other writers, makes errors in his work. Numerous errors have

been detected by Laplace's commentators, but the secular acceleration occupies quite a distinct position. It must be remembered that the calculations of Laplace appeared to render a physical explanation of a remarkable phenomenon. But when this calculation was shown to be seriously wrong, it followed that the cause of the secular acceleration conjectured by Laplace was inadequate to explain the observed facts. The labours of Adams thus reopened the breach between the observations and the theory. The variations in the eccentricity of the earth's orbit will account for part of the secular acceleration. The other part has to be accounted for in a different way. The theory of the tides seems to offer an explanation of the discrepancy. Owing to their incessant action the period of the diurnal rotation has been slightly elongated, and this effect, when duly taken account of, seems to remove the margin between the theoretical and observed values of the secular acceleration. This margin has indeed a singular interest in the recent theory of tidal evolution, inasmuch as it affords us the only measurable indication we have of the effect of tides on the earth's rotation.

The splendid shower of shooting-stars that occurred in November 1866 fixed the attention of astronomers on every part of the theory of these bodies. We were thus taught much concerning them, but for one of the most recondite parts of their theory we are indebted to the labours of Prof. Adams. It had been known that the great displays of the Leonids (for so these shooting-stars are called) take place every thirty-three years. From the year 902 down to the year 1866 many of the successive thirty-three-year periods witnessed the great shower, and records of a considerable number have been handed down to us.

These minute bodies must revolve around the sun, each pursuing its orbit in accordance with the laws of Kepler. It became of interest to find the size and shape of this orbit, as well as its position. Certain features of the orbit are readily determined. The recurrence of the shower on a particular day of the year gives one point in the path of the meteors. The direction of the radiant gives a tangent to that path, and therefore its plane. The sun, of course, lies at the focus, and only a single further element—the periodic time—is requisite to complete our knowledge of the orbit. We are indebted to Prof. H. Newton, of Yale, for his careful discussion of this subject. He had shown that the choice of possible orbits was limited to five. There was first the great oval orbit, in which we now know the meteors do revolve every $33\frac{1}{4}$ years. There was next a nearly circular orbit, with a periodic time a little more than a year; another similar orbit, in which the periodic time would be a few days short of a year; and there were also two other smaller orbits. Prof. Newton had also indicated a method by which it would be possible to discriminate the true orbit as one of these five. The mathematical difficulties of this method were no doubt great, but they did not baffle Prof. Adams.

In the *Monthly Notices* for April 1867, p. 247, will be found the paper in which he announced his solution of the problem. The orbit of the meteors is not fixed, but every time the great swarm comes round, the node is found to be 29′ further on in the direction of motion. The effect of this is shown in the gradual alteration of the date of recurrence of the shower. The only influence known to us which could account for this change of the plane, is the attraction of the other planets. The problem, then, may be placed in this shape. A certain specific amount of change of the node takes place. The theoretical change can be computed for all the five different orbits, and Prof. Adams undertook to find it. The difficulty principally arises from the high eccentricities of some of the orbits, which rendered the more familiar methods of calculation inapplicable. After many months of labour, Prof. Adams, aided by his assistants in the Cambridge Observatory, completed his work. He showed that if the meteors revolved in the large orbit with the periodic time of $33\frac{1}{4}$ years, the perturbations of Jupiter would account for a change to the extent of 20′. The attraction of Saturn would augment this by 7′, and Uranus would add 1′, the effect of the earth and the other planets being insensible. The joint effect is thus 28′, which may be regarded as practically coincident with the observed value determined by Prof. Newton. The great orbit was thus a possible path for the meteors, but to complete his discovery Adams had to show that neither of the other four orbits could experience the same perturbation. This, too, he succeeded in demonstrating: he showed that in no one of the other orbits could the change exceed 12′. Thus the orbit of the Leonids was discovered.

Those tremendous powers of calculation which have been exercised on the heavenly bodies with such signal results have also been occasionally applied in various other directions. The discoverer of Neptune has found relaxation from the labours of physical astronomy by little calculations on which we must gaze with astonishment. He has had the curiosity to compute the sums of the reciprocals of the first thousand numbers to 260 places of decimals. We have such confidence in the accuracy of Prof. Adams that we have not thought it necessary to repeat this calculation! He has also taken the trouble to calculate thirty-one of Bernouilli's numbers beyond the point that previous calculators had attained, and he has expressed each of them both as vulgar fractions and as decimals. The sixty-second Bernouilli, the last computed by Adams, runs to 111 places, where fortunately for astronomy the appearance of a recurring figure has terminated this inquiry.

Need it be added that on Prof. Adams every honour which science can bestow has been conferred. We have now the pleasure of enriching our list of Scientific Worthies by the addition of his portrait. R. S. B.

THE BRITISH MUSEUM BIRDS

Catalogue of the Birds in the British Museum. Vol. XI. Fringilliformes: Part II. Containing the Families *Cærebidæ*, *Tanagridæ*, and *Icteridæ*. By Philip Lutley Sclater. (London: Printed by order of the Trustees. 1886.)

DR. GÜNTHER and the authorities of the Natural History Department of the British Museum are to be congratulated, first, on having sought, and next on having secured, the services of Mr. Sclater for the execution of the eleventh volume of their "Catalogue of Birds." The principal group of which it treats is one that has been, for five-and-thirty years or more, the

favourite subject of his study, and indeed there are people who hardly hesitate to assert that the final cause of the existence of the family *Tanagridæ* must have been to find occupation for that gentleman's ingenuity in discriminating, describing, and disposing its members.

In consequence of this the present volume of this "Catalogue" appears as a finished piece of work. Whatever may have been the faults of the plan on which the whole was designed, here its defects are reduced to a minimum, so that few are made manifest. The relationship of the *Cærebidæ* to the *Tanagridæ* is outwardly pretty close, and there is as yet no indication that future research into their inward structure is likely to separate them more widely, though in the existing state of ornithotomical study it would not be safe to say more. Granting, then, as Mr. Sclater considers, that the former of these families is so nearly allied to the latter that "it is indeed somewhat difficult to separate them by external characters," the comprehension of these two groups in one and the same volume is a very natural proceeding. As regards the third family, *Icteridæ*, associated with them on the present occasion, opinions may reasonably differ. Mr. Sclater confesses himself open to doubt on this point; and, if he does so, a slight amount of agnosticism may be pardoned in others who know not one-half so much about them as he does. Possibly if he had referred to some remarks of Prof. Parker's (*Trans. Zool. Soc.*, x., pp. 266, 267) on the relations of this group, the matter might have seemed to him a little clearer. Mr. Sclater's belief is that, since these birds "present many points of alliance with" the *Sturnidæ*, *i.e.* the true Starlings of the Old World, it would therefore be better "to place them *after* the *Fringillidæ*." Now the multitude of "points of alliance" is perhaps rather apparent than real, and though Prof. Parker considers (*loc. cit.*) that the *Icteridæ* and *Sturnidæ* cannot be "considered to be unrelated," he also shows that the former have nearer allies in their own part of the world. But this by the way. It is more important to inquire in what sense the word "*after*" is used by Mr. Sclater in the passage just quoted. We may be sure that he does not entertain a notion of the possibility of deploying any part even of the animal kingdom in a straight line, as was of old time thought not only possible but expedient; for such a notion would be completely at variance with the doctrine of evolution, which he of course holds. If the word "after" is merely intended to refer to the purely arbitrary arrangement followed, or to be followed, in the "Catalogue," it signifies nothing, and we have no cause to complain. Again, if "after" is to be understood in the sense of "inferior to," then we should wholly agree with him. But if the procession of forms be contrariwise arranged—there being no evidence in this volume to show whether this is so or not—and by the word "after" a later and consequently higher or more specialised type be indicated, then we should, with all deference, beg leave to demur to the supposition. Whatever be the rank and proper place among the true *Passeres* of the *Fringillidæ*—and Dr. Stejneger has lately propounded the view that theirs is the highest—the fact should always be remembered that the so-called *Fringillidæ* of many systematists certainly contain at least two groups, which in their more advanced stages can, so Prof. Parker tells us, be always discriminated. These two groups are the Finches proper and the Buntings, which last several taxonomers have recognised as forming a family, *Emberizidæ*, equal in value to the restricted *Fringillidæ*. Now Prof. Parker has shown that it is to the *Emberizidæ* rather than to these *Fringillidæ* that the *Icteridæ* are allied, and it therefore becomes important to determine the limits of the *Emberizidæ*, which, owing to the want of anatomical or morphological research, is admittedly hitherto a matter of guesswork. In regard to those members of the former which belong to the Old World, or are common to it and to the New World, no difficulty has as yet presented itself. It is in the New World alone that the doubtful forms exist; but even of some genera peculiarly American—*Phrygilus*, for example, as proved by Prof. Parker—indication is not wanting; and if we might hazard a supposition on the subject, it would seem on several grounds more likely that a closer alliance should be shown to exist between the *Icteridæ* and the *Emberizidæ* than between the latter and the true *Fringillidæ*.

From what has been submitted in the foregoing sentences, those who can "read between the lines" may perceive that underneath the points just touched upon is a question of much greater significance than is ordinarily presented by matters of mere taxonomy—especially of the taxonomy of a group of birds so homogeneous as are the *Passeres*. It is undeniable that the American forms of this multitudinous and confessedly highest group of birds (with the exception of those which, being so closely related to the Old-World forms may be not unreasonably supposed to be their derivatives) show a great preponderance of the weaker and, morphologically speaking, lower types. It is in the New World, and especially in South America, that we find all the *Tracheophonæ* and a majority of the different groups of *Oligomyodi*.[1] We can hardly doubt that these are as nearly autochthonous as any groups which now exist; that is to say, they had their origin on land which is now represented by the American continent. Though analogy is often a deceitful guide, it does not seem irrational to urge the same of the *Oscines*. Among them it is certain that not one of the three families which different systematists have selected for the post of leader is strongly represented in the New World—two of them, the *Corvidæ* and *Fringillidæ* (if we exclude the presumed *Emberizidæ*), very poorly indeed; while the remaining family, *Turdidæ*, cannot number, even at a very high estimate, one-third of its members as American. The meaning of these considerations will become plainer if we substitute for the expression "weaker and lower types" its justifiably equivalent rendering, that of "older and more generalised types." Then we shall see the important signification of the alliance we have supposed to exist between the *Icteridæ* and the *Emberizidæ*; and, moreover, a reasonable means of accounting for the remoter relationship, recognised by Mr. Sclater (Introd., p. viii.), between the *Tanagridæ* and the *Fringillidæ* on the one hand, and the *Cærebidæ* and *Mniotiltidæ* on the other, is provided. This result, we trust, will serve to excuse these remarks, which might otherwise appear to be irrelevant; and, speculative as

[1] To attempt here to account for the distribution of the non-American families of this group—*Pittidæ*, *Philepittidæ*, *Eurylæmidæ*, and *Acanthisittidæ*—would lead us far beyond the limits of our present subject.

they are, it must not for a moment be imagined that we think the introduction of anything like them was needed or would have been expedient in such a volume as that now under notice. A reviewer may take liberties that are denied to an author.

But now to return to our proper business. In his treatment of the subject Mr. Sclater, as might be expected, shows himself its master; not but that there are a few points—and one of them we have indicated—on which he owns himself doubtful. This is no drawback, for such there are, and long will be, in every matter of this kind. One great merit, in our eyes at least, is that he steadily treads the old high-road which has conducted its passengers to so many great achievements, and refuses to follow the bewildering by-paths, of late so much vaunted by various writers, that are eventually found to mislead the unwary or inexpert traveller into bottomless bogs. A plain view of things is taken, and one that is suggested no less by eminent knowledge than by common-sense. There is no attempt to regenerate a fallen world of science within the narrow limits of a catalogue, or to make the catalogue of a single museum, however great its wealth, pass for a monograph. From the beginning of the volume to its end there does not appear the trace of a wish to indulge—may we be pardoned the word?—a "fad"; not even in the frivolous matter of nomenclature, a rock on which all novices are sure to strike, and often to split.[1] The various "keys" with which every group is provided seem always to fit and to turn easily in their locks—not, indeed, a surprising fact, since Mr. Sclater, if not the inventor, has long been one of the most skilful handlers of this convenient differentiating instrument, so useful when manufactured by an adept, and so useless when turned out by a tiro, who not seldom contrives, in the course of a few lines, so to complicate his conditions (of his own choosing, be it remembered) as to render them characterless, if not contradictory. To sum up, it may be said that, supposing the plan of the British Museum "Catalogue of Birds" to have been well laid, Mr. Sclater has shown how it may be well executed.

THE VITAL STATISTICS OF GLASGOW

The Vital Statistics of the City of Glasgow. Part II. The Districts of Glasgow. By James B. Russell, M.D., LL.D., Medical Officer of Health.

IN this Report Dr. Russell presents us with the vital statistics of the city of Glasgow and its districts for 1880, 1881, and 1882, and with some comments on, and inferences to be drawn from, the facts enumerated. Some years ago an Improvement Trust scheme for the sanitary reformation of the houses of the people was elaborated and put into operation. This scheme has achieved "a summary revolution in the worst parts of the city," not apparently before it was wanted, for Dr. Russell shows that some of the districts of Glasgow—notably that known as Bridgegate and Wynds—do not compare favourably even with the worst slums of London or Liverpool. Bridgegate and Wynds had a death-rate for 1880, 1881, and 1882, of 38·3 per thousand, a birth-rate of 37·1 per 1000, a death-rate under one year per 1000 born of 206, and a death-rate from consumption and acute diseases of the lungs of 16·75—this figure alone being higher even than the total death-rate of many English towns. Much of this district has been improved off the face of the earth—the population in 1881 was 7798, in 1871 14,294—still the houses that are left "are radically bad, and total demolition and destruction is the only remedy." It is such districts as these that have, as Dr. Russell remarks, "been the heartbreak of successive generations of Glasgow philanthropists." The death-rate of the city of Glasgow, as a whole, for 1880, 1881, and 1882, was 25·2 per 1000, with a birth-rate of 37·3 per 1000; although considerably less healthy than London, Glasgow compares favourably with Dublin, and stands on about the same level as Liverpool and Manchester. The death-rates of the different districts of the city in 1871–72—prior to the improvement schemes—are compared with those in 1880, 1881, and 1882, subsequent to the carrying out of many improvements in unhealthy areas by demolition and reconstruction. The comparison shows that in all the districts the general death-rate and the death-rate under five years (with one exception) were much lower in the latter period than in the former. "This result," Dr. Russell remarks, "is important, as proving that the displacement of the inhabitants of the central parts of the city has not deteriorated the health of the districts into which they have removed. It was proved by special investigation that the people whose wretched houses were demolished by the Improvement Trust distributed themselves over the city. It is often said that the habits of these people are such that, go where they please, they will not be the better of the change. It is evident, however, that they found physical conditions so much more conducive to health that, whether or not their habits have been improved, undoubtedly their health has been, in their new residences. The moral is to persevere in the destruction or improvement of the houses of the people. The certain result is to improve their health."

The influence of overcrowding on mortality, and the connection subsisting between overcrowding and an Irish population are well shown in the contrast between two of the districts. Blythswood is remarkable as having the lowest proportion of inmates per inhabited room, the largest proportion of large-sized houses, the lowest death-rate, the lowest birth-rate, the lowest mortality under five years, the lowest proportion of deaths under one year per 1000 born, and the lowest proportion of Irish-born of any district in Glasgow. Bridgegate and Wynds, on the other hand, has the largest proportion of inmates per inhabited room, the largest proportion, save one, of one-apartment houses, the highest death-rate over all, the highest death-rate under five years, the largest proportion of deaths under one year per 1000 born, and the highest percentage of Irish-born inhabitants. And in general, Dr. Russell states it to be a fact "that a district which has houses occupied *above* the standard number of persons per room (*i.e.* above the mean number of the whole

[1] Indeed, we think we should have ground for complaining that Mr. Sclater has not made one nomenclatural change. He is of course as well aware as any one that the idea of a generic type never occurred to Linnæus, though it was ever present with Brisson. Nevertheless, modern specialists are required to find a type for every Linnæan genus; and, despite the almost universal practice, the type of *Tanagra* (which is only Brisson's *Tangara* with a modified spelling) is clearly *T. tatao*. Moreover, the generic term *Calliste*, used by Mr. Sclater for that species and its congeners, is but questionably admissible from its prior application by Poli ("Test. utr. Siciliæ," i. p. 30)—in a different dialectical form (*Callista*), it is true; but the Goddess of Wisdom may be called to witness that her name, whether written Athen*e* or Athen*a*, is one and the same; while we ask her pardon and that of our readers for drawing attention to such a trifle.

city), has a general death-rate *above* the standard death-rate of the city, an infantile death-rate *above* the standard infantile death-rate of the city, and especially that the fatality of those diseases which are directly related to overcrowding or deficiency of breathing-space—viz. diseases of the lungs and infectious diseases—is in excess in those districts."

Dr. Russell also discusses such subjects as the percentage of uncertified deaths, and the insurance of lives in friendly societies, the relations of legitimacy and illegitimacy to certification and insurance, and their bearings on the social conditions of poor populations—subjects of great interest to philanthropists and sanitary reformers, as indicating the instincts and habits of so large a mass of our poor populations. The rest of Dr. Russell's Report is of more purely local interest; but enough has been said to show that Glasgow, if it has been in want of sanitary reform, has not been behindhand in what may be described as one of the greatest works of the age, and that philanthropy in this case has met with its due reward in the vast improvements effected in the social condition of the people.

THE FRESH-WATER FISHES OF EUROPE

The Fresh-Water Fishes of Europe. A History of their Genera, Species, Structure, Habits, and Distribution. By H. G. Seeley, F.R.S., &c. With 214 Illustrations. 8vo. Pp. vi. and 444. (London, Paris, New York, and Melbourne: Cassell and Co., 1886.)

A WORK containing an original, exhaustive, and critical account of the fresh-water fishes of Europe, such as might bear the title heading this notice, would be an undertaking which would require on the part of the author a thorough acquaintance with ichthyology, considerable experience with the method of ichthyological research, an autoptical examination of many of the types preserved in the various European museums, and, finally, the formation of a collection more complete than the combined series of European fresh-water fishes in the museums of London, Paris, Vienna, Berlin, and St. Petersburg; in fact, an undertaking that would occupy the greater portion of a life-time, and stand as a monument of which any naturalist might be proud.

We have too high an opinion of Prof. Seeley's abilities to doubt for a moment that he might have produced a standard work of this nature, if he had chosen to devote the requisite time and labour to it. But what he has really accomplished is merely a compilation from the standard works mentioned in his preface, without the addition of any new facts or observations, and without any attempt at such a critical treatment of the subject as might be expected from an author acquainted with the objects described. His book, in fact, might have been compiled in the author's own library or in that of the British Museum without his looking at a single fish. The illustrations are no less wanting in originality; with the exception of half-a-dozen anatomical figures familiar to every ichthyologist, the remaining 208 are simply borrowed from Heckel and Kner, "Süsswasserfische der östreichischen Monarchie"; and consequently no fish peculiar to any other part of Europe or absent from the Austrian fauna is represented in the book. It should be remembered, however, that at the date of their publication (1858) the two Austrian ichthyologists above named were enabled to include in their fish-fauna a number of the species of Northern Italy. We think that the source whence the illustrations were taken should have been stated in the preface.

As regards the usefulness of the book, there cannot be any doubt that a handy book on the fresh-water fishes of Europe was a great desideratum. A glance at the natural-history columns of the *Field*, *Land and Water*, and other weekly papers shows the great number of travellers on the Continent who seek for information about fresh-water fishes which are strange to them, and to whom the original works wherein they could find it are either unknown or unintelligible. For this large class of the non-scientific public Prof. Seeley has supplied a real want and a useful book of reference, the utility of which would have been much greater could he have induced his publishers to go to the expense of figuring other fishes besides those found in Austria; and we cordially join him in the hope "that the fabric of the work will give a new interest to the fishes of our own country, and may influence British peoples to a thrifty cultivation of the roving wealth which swims, little heeded, in our forms of fresh-water fish life."

OUR BOOK SHELF

Papers in Inorganic Chemistry. Part I. Non-Metals. Part II. Non-Metals and Metals. By George E. R. Ellis, F.C.S. (London: Rivingtons, 1886.)

THIS is a collection of examination questions arranged progressively, and is intended for the use of science teachers and students. The idea is a good one, and we have no hesitation in saying that the book will be appreciated by those for whose benefit it has been compiled. Although we are far from approving of the present mania for examinations, we agree with the author that the conscientious answering of well-selected questions is of great advantage to the student. It not only tests his knowledge gained from text-books and from lectures, but it renders it more accurate and permanent.

The solution of chemical problems is generally a weak point with beginners, and we are glad to see a fair proportion of such problems in Mr. Ellis's book. There are, however, a few arithmetical questions which appear a little out of place in papers in inorganic chemistry. On p. 6, for instance, there is one on the tonnage of the s.s. *Oregon*, and others may be found on pp. 10, 12, 30, &c.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

Our Guns

YOUR article on the above (p. 517) induces me to repeat an appeal which I made ten years ago in a paper on "Explosive Compounds," contributed to Stanford's "British Manufacturing Industries." I there pointed out the enormous discrepancy between the results obtained in the testing of the pressure exerted by the explosion of gunpowder by the Government Committee on Explosives and those of Count Rumford made in 1793, and described in his essay on "The Force of

Fired Gunpowder" (published in London, 1802, and recently reprinted, with his other essays, in America).

Our Government official experiments give a pressure per square inch varying from 15·4 to 28·1 tons per square inch, the latter obtained in the 81-ton gun. Rumford's maximum was 277 tons, as shown by overcoming the tested tenacity of metal that the powder tore asunder; or 73 tons, as indicated by the lifting of a weight by the explosive energy.

As I explained in the paper above named, the tearing test is fallacious as a theoretical measure of the force exerted, because the tenacity of the metal was tested by Rumford, as it still is by others, in most cases, by a gradually-applied strain, which should not be compared with a vibratory shock. As a measure of the practical bursting possibilities of gunpowder upon metal of given thickness and tenacity, as usually measured, Rumford's figures are directly applicable, though allowance must be made for the relief afforded by the movement of the shot in a gun.

My appeal was for a repetition of Rumford's experiments by those who are responsible to the nation for these very serious matters, and for a reconsideration of the reliability of the method of testing by the "Rodman" and "Crusher" gauges, which have supplied such very different results from those of Rumford. My reasons for believing Rumford's experiments to be more reliable than those of the Committee were stated as follows, and I still maintain their cogency:—

"(1) The resistance to be overcome, and by which the force was measured, viz. the gravitation of a known weight, was by far more definite and measurable than the degree of indentation or compression of a cylinder of copper, which serves as the measure of force in the Rodman and Crusher gauges.

"(2) In Rumford's arrangement the force of the explosion was more directly applied to the resistance by which it was measured than in the official experiments, where the shock of the explosion was first communicated to a solid piston 1 inch in length, and by this transferred to the copper cylinder of the Crusher gauge or the knife of the Rodman gauge. By this arrangement much of the force is expended upon internal work in the intervening piston, producing mechanical vibration of its substance, and a returning wave of elastic compression, which would have no measurable effect on the gauge. Besides this, another portion of the force compressing the piston must be converted from mechanical motion into heat motion.

"If any reader supposes that I am hypercritical in making this objection, let him try the following experiment. Take a block of iron—a common 1 lb. weight, for example—place it on the hand, and the hand upon a table; then strike the weight smartly with a carpenter's hammer. It will be found that blows which would fearfully mutilate the hand if directly applied to it, may be struck upon the weight thus resting entirely upon the hand, and will scarcely be felt, provided the blows are dealt suddenly and smartly. The mountebank's exploit of breaking a great stone upon a man's bare breast, the common method of reducing the dimensions of geological specimens by holding them in the hand and cracking with a hammer, and the experiment of shooting a bullet through a swinging door without moving it on its hinges, are familiar illustrations of this principle, which appears to have been overlooked in these official researches.

"The complete absence of windage in Rumford's arrangement, by exploding in a perfectly closed chamber, is a third advantage. I therefore regard Rumford's experiments as the best that have yet been made on this interesting subject, although, as he himself admits, they are by no means free from error."

W. MATTIEU WILLIAMS

Photographs of Stellar Spectra

THE article upon this subject in NATURE, vol. xxxiv. p. 439, requires a correction which has been pointed out by Dr. Copeland. The spectrum of the star DM. + 37° 3821 was observed by him on September 22, 1884, and found to contain bright lines; the observation was published in the *Monthly Notices* for December 1884, but was overlooked at the time when the article above mentioned was prepared.

A similar correction, pointed out by Dr. Huggins, is required in the "Investigation in Stellar Photography" by the present writer, published in vol. xi. of the "Memoirs of the American Academy of Arts and Sciences." On p. 208 the method of observing stellar spectra by means of a prism placed before the object-glass of a telescope is ascribed to Secchi. In fact, it had previously been employed by Fraunhofer.

EDWARD C. PICKERING

The Late American Earthquake and its Limits

IN your very flattering *critique* of my "Alphabetical Catalogue of European Earthquakes" the reviewer says:—"The tendency to alignment in volcanoes has often been noticed; Prof. O'Reilly indicates a similar peculiarity in earthquakes, adding that the lines along which they range approximate to great circles. This inference or suspicion can be verified only by detailed charting." Judging from the facts published up to the present relative to recent earthquakes of America and Europe, I think some such verification has been furnished by them. At the Exhibition of Scientific Apparatus held at South Kensington in 1877, I exhibited a globe mounted so as to allow of great circles being easily traced through points on the surface. Several coast-line great circles were shown thereon, amongst them that of the southern boundary of the Tertiary formation in the United States. It was also marked on the sketch earthquake-map of Europe exhibited before the Section of Geology of the British Association at their Swansea meeting of 1882, and on other maps, such as the earthquake map of the British Islands; and yet no leading fact went to prove that any particular significance should be attached to this great circle. The earthquakes of August 27 and 28 in the United States have furnished, in my opinion, some proofs of this significance. The following are the places through which this great circle passes:—Victoria Fort, on coast of Gulf of Mexico; Cairo (Ill.); axis of Lake Erie; Lake Ontario; River St. Lawrence (parallel to); New Brunswick coast of River St. Lawrence; Labrador, south coast; York Point and Straits of Belle Isle; Ireland, Shannon mouth; Wales, south coast of; St. Bride's Bay; Mendip Hills; Southampton; Dieppe, north of; Chalons; Bâsle, north-east coast of Zurich Lake; Coire; Trent; Venice; Dalmatian coast; south-west coast of Isola Longa; Mount Olympus; Skyro Island; Syrian coast, head of Akaba Gulf; Arabia, Mount Seiban, Wady Maifa; Cape Guardafui; Pacific Ocean, Paumota Group; coast of Mexico, near Cape Corrientes; Zacatecas territory.

According to Major Powell's telegram, the origin of the earthquake was along a line of post-Quaternary dislocations on the eastern flank of the Appalachian Chain, especially where it crosses North Carolina. The great circle just described passes more inland than that mentioned by Major Powell, and was taken, as regards position, from the geological map of the United States, by C. H. Hitchcock and W. P. Blake, 1873, but it is parallel to the line limiting the Tertiary formation which crosses North Carolina, and which is probably also the seat of the post-Quaternary disturbance referred to. The great circle in question traverses the area of disturbance between Kennett (Ark.) and Buffalo (on Lake Erie). On the European side the following places lie near its direction. The Bristol coal-fields, where an explosion of fire-damp took place lately, about the time of the earthquake; the English Channel, lat. N. 50° 10′ and long. W. 1° 40′, where an earthquake shock is reported to have occurred by H. Mohn in your issue of September 23 (p. 496); the point lying about fifty-five miles to the south of the great circle, where it passes at Southampton. Switzerland: M. Forel reports in your journal of the 16th ult. (p. 469) a series of shocks in the western part of Switzerland having occurred in the first days of September, and which he considers as the *suite* of the earthquake of August 27. In Eastern Europe an earthquake occurred on this same date, which travelled eastward from Malta to the South of Italy and reached Smyrna, which lies somewhat to the north of the great circle. In Mexico an earthquake is reported as having occurred at Tequisextlan on the 3rd ult. I can find no such place, but if it be the same as Tepantitlan, about fifty miles east-north-east of Guadalajara, it would be somewhat south of the great circle in question. As all these places are not far removed from the direction of the great circle, and as there must be several parallel lines of fissuring in the Appalachian Chain, thus forming a zone, there is in this way, I think, evidence furnished that a zone of seismic action exists, having the general direction of the great circle represented by the continuation of the boundary-line of the Tertiary formation in the United States to the west of the Mississippi Valley, as marked on the geological map of Messrs. Hitchcock and Blake.

In the map forwarded herewith I have defined the surface of disturbance by lines joining the extreme points mentioned as having suffered shocks; but further information may, and probably will, modify this outline. The polygonal form thus obtained is, I think, more satisfactory than the curved forms

usually adopted, since there are some grounds for thinking that the limits of disturbance are generally lines of faulting or limits of formations. In the first report received, the extreme points mentioned to the west were Jacksonville and Chicago, both situated on a line which represents the axis of the promontory of Florida, as shown by the map. The great mass of the surface shaken lies to the east of this line, so that this surface would be bounded by coast-line directions, at least partially. When fuller information comes to hand, I trust to be able to show more perfect results in this respect. J. P. O'REILLY

Algebraic Notation of Kinship

MR. F. GALTON has described two systems of kinship notation: one in his work on "Hereditary Genius," pp. 50 53; the other in a letter to NATURE, vol. xxviii. p. 435. I propose to indicate here the outline of another system, which, though slightly more cumbrous in form than Mr. Galton's, seems to me to possess some advantages of its own.

Let us denote the male members of a family by a capital letter, say F, females by a small letter, *f*. Taking the person described as a starting-point, relatives in different generations may be denoted by *indices* attached to these letters. For relatives in the same generation, the index is 0; for those in the first, second, &c., generation before him, the indices are 1, 2, &c.; for those in generations following him they are −1, −2, &c. Thus, a brother would be denoted by the symbol F^0, a sister by f^0; the father by F^1 and mother by f^1; a son by F^{-1} and a daughter by f^{-1}. Again, the father's father would be denoted by $F^1 F^1$, or more shortly by F^2; the father's mother by $F^1 f^1$; a son's son by F^{-2}, a daughter's son by $f^{-1} F^{-1}$; the father's brother by $F^1 F^0$ (or perhaps by F^{10}, if it be remembered that here 10 stands for 1 + 0, and not for ten, which is too large a number to be often required); the mother's brother by $f^1 F^0$; the father's sister's son by $F^1 f^0 F^{-1}$, and her daughter by $F^1 f^0 f^{-1}$; and so on. The advantages of the system are: (1) that it is readily used and interpreted; (2) that the generation of any relation with respect to the person described may be found at once by adding the indices of his kinship symbol. For example, in the last two instances given, the sum of the indices is 0, showing that in both cases the generation is the same as that of the person described.

The simpler relationships are shown in the following table:—

F^2 Grandfather = $F^1 f^1$ Grandmother | $f^1 F^1$ Grandfather = f^2 Grandmother

$F^1 F^0$ Uncle | $F^1 f^0$ Aunt | F^1 Father = f^1 Mother | $f^1 F^0$ Uncle | $f^1 f^0$ Aunt

F^0 Brother | PERSON DESCRIBED | f^0 Sister

$F^0 F^{-1}$ Nephew | $F^0 f^{-1}$ Niece | F^{-1} Son | f^{-1} Daughter | $f^0 F^{-1}$ Nephew | $f^0 f^{-1}$ Niece

F^{-2} Grandson | $F^{-1} f^{-1}$ Granddaughter | $f^{-1} F^{-1}$ Grandson | f^{-2} Granddaughter

If desired, suffixes to the letters might be added to denote the position in his family of any person noted in the kinship symbol. The symbol $F_3^{-1} f_5^{-1}$ would, for example, denote a son's daughter, the son being the third member of his family, and his daughter the fifth. CHARLES DAVISON

Birmingham, September 30

Physiological Selection

AS Dr. Romanes has had his attention drawn to my letter (NATURE, vol. xxxi. p. 4), he may be interested in knowing just how far his theory of physiological selection was anticipated by what was in my mind.

My idea was that a spontaneous variation might occur in the sexual elements of the offspring of one parent or pair which would leave them fertile with each other, while rendering them almost or quite infertile with the rest of the species, so that the family would be physiologically insular.

Though I did not definitely so limit it, it did not seem to me likely that a corresponding change in both sexes, which was what I had in my mind, would occur, except in the offspring of the same parent or pair; and I rejected the idea of a gradually increasing infertility in favour of a total or nearly total infertility arising in the one generation, because I did not see any cause for the continuous increase from generation to generation of such infertility.

It did not occur to me that a partial infertility would, in a number of generations, produce the same result, as pointed out by Dr. Romanes (NATURE, August 5, p. 316). Nor do I now see clearly that it would ever lead to the total infertility which exists between species which have not otherwise diverged very much. At present, however, I only wish to point out that the idea of gradually increasing infertility was in no way anticipated by me. EDMUND CATCHPOOL

American Vines

IN reading Prof. Carruthers' very interesting address to the Biological Section of the British Association, I observe that he says, when speaking of the vine discovered by Dr. Schweinfurth at Abd-el-Qurna: "The leaves which have been obtained entire exactly agree in form with those cultivated at the present day, but the under-surface is clothed with white hairs, a peculiarity which Dr. Schweinfurth has not observed in any Egyptian vines of our time." Will you allow me to remark that this is a character of several of our American vines? Both the Northern Fox and the Summer Grape (*V. Labrusca* and *V. æstivalis*) are conspicuously downy on the lower surface of the leaves—so much so that they appear white.

This fact adds another to the list of points in which the old flora of the eastern hemisphere resembles that now existing on the western side of the Atlantic. But the resemblance in this case is of much more recent date than those with which we are so familiar from the researches of Prof. Heer among the Oeningen beds of Switzerland.

In connection with the facts above mentioned, it would be of interest to ascertain if an opportunity should ever occur whether the other noteworthy differences between the American vines generally and the European vine, namely, the musky or foxy flavour and the soft and pulpy, not firm and fleshy, berry were accompaniments of the downy leaf. This may never be possible, but it would serve to show which of the two was the older stem from which the other has diverged. E. W. CLAYPOLE

Akron, O., U.S., September 30

"Scopelus mülleri"

A FEW weeks since I received a letter from Mr. Southwell, of Norwich, wherein he informed me that Capt. Gray had sent him a very interesting fish, which he kindly forwarded to Cheltenham. He captured it on August 1, 1886, in lat. 73° 12′ N., and long. 14° 28′ W. Capt. Gray remarked:—"It was at the surface; I noticed it while away in a boat as I leant over the bow and watched the water as it passed. It was covered with bright golden scales when I first found it, but they are nearly all rubbed off. It was alive when I picked it up, and the temperature of the water was 35° F., and that of the air 35° also."

The specimen is in comparatively a good state of preservation; the tail, however, has been broken, reducing its total length to 2 inches; from the snout to the base of the caudal fin, 1·8 inch.

D. 14, P. 11, V. 8, A. 16, C. 19, L.l. 36.

Its proportions are normal, agreeing with Collett's description, the origin of the dorsal fin commencing exactly midway between the end of the snout and the base of the caudal fin. As good examples appear to be very rare, I propose remarking on certain appearances which have been in dispute. The eye-like spots are thus disposed: along the edge of the abdomen, between the throat and base of the ventral fins, 5 pairs; between the ventral and anal, 3 pairs; along the base of the anal, 8 pairs; beyond the anal, 6 pairs. Krüger gave a similar number between the ventral and anal to what exists in this specimen, but Collett found 4 pairs there. Between the 6th and 7th pairs along the base of the anal fin, and between the 5th and 6th pairs behind that fin, there is a wider space than between the others. Along the side and below the posterior half of the lateral line are two more of these eye-like spots, while a row of three passes from

the anterior of these to the subopercle. Another spot exists at the shoulder above the gill-opening, and an indistinct one on the edge of the preopercle.

The figure in the magnificent work of the "Fishery Industries of the United States," plate 202, agrees with this specimen in the proportions of the body and length of the fin-rays; but, supposing the species to be the same, differs from it materially in some other points. The position of the dorsal fin is shown too far forward; the scaling is not identical, as the lateral line in Capt. Gray's specimen stands upon a narrow but vertically elongated row of smooth scales, having three rows of smaller ones above it, and four below it; also the eye-like spots are not similarly placed, and the pectoral fin is narrower, with its rays more elongated. The Sense of Smell

WITH reference to Mr. Mitchell's inquiries (NATURE, September 30, p. 521), there is a peculiarity about musk which I have never found anybody to be previously aware of, namely, it is impossible to smell it *twice*, taking two good "sniffs" consecutively at a plant, *i.e.* after a single exspiration; on the second inspiration there is no odour of musk whatever.

GEORGE HENSLOW

Humming in the Air caused by Insects

YOUR correspondent who writes on the above subject in this week's number of NATURE (p. 547) remarks that "It is singular that no explanation has been offered by any one for such a common phenomenon." May I be allowed to refer him to my "Observations in Natural History" (published in 1846), p. 226, where I have given a statement of my own on the subject, adding a reference to Humboldt's "Personal Narrative," in which he makes some remarks on this humming, as heard in the tropical regions, where the phenomena is naturally so much more striking, and on a wider scale.

There can be no doubt the explanation of the phenomenon given by your correspondent is the correct one.

Bath, October 9 LEONARD BLOMEFIELD

THE HONG KONG OBSERVATORY

DR. W. DOBERCK, Government Astronomer at the above Observatory, has recently published an official report on the astronomical instruments under his charge, and on the time service of Hong Kong in 1885, the determination of local time being the chief purpose of the astronomical branch of the institution.

The Report states that the Observatory possesses a transit instrument, by Messrs. Troughton and Simms, of 3 inches aperture and 3 feet focal length. Setting in declination is effected by means of two small circles fixed on the telescope near the eye-end, and read by levels. The axis is perforated for side lamps. The pivots, which are made of chilled bell-metal, show no perceptible difference between their diameters, but minute irregularities appear to exist, though too small to allow their exact amount to be determined by means of the axis level This level is used in determining the inclination of the axis, and another similar level is provided for use with the zenith micrometer in the observation of differences of zenith distances on either side of the zenith.

The eyepiece was originally furnished with one movable and seven fixed vertical wires, but the latter after a little while began to get entangled with the fixed wires, and finally broke. Although it had been found very useful in the determination of the instrumental constants, it was not thought well to replace it for fear lest the permanent wires might become disturbed or broken by it. Transits were at first observed over all the seven wires, but in 1886 only the five middle wires have been used. There are also two horizontal wires about a minute of arc apart, and the object the transit of which is to be observed, is brought midway between them. The eyepiece and wire system can be revolved through a quarter of a revolution, so that the vertical wires become horizontal, and can be used for determining the differences of zenith distance for latitude; but as the instrument is in constant use as a transit, this arrangement has never been made use of, there being the less necessity for employing it, as Col. Palmer had accurately determined the latitude of the Observatory in 1882.

The telescope rests upon a cast-iron stand with reversing apparatus; no change in the inclination has ever been perceived to be caused by the reversion. The stand rests on a slab of Portland stone on the top of a brick pier sunk 5 feet in the ground, where it is surrounded by a brick cylinder to protect it from surface oscillations.

In 1884 505 transits were observed; in 1885, 313; the inclination of the axis was observed 150 times in the former and 117 in the latter year. A meridian mark, which is viewed through an object-glass of about 66 feet focal length is placed about 70 feet to the north of the transit instrument; another meridian mark is 11,354 feet to the south across the harbour.

The standard sidereal and mean time clocks were supplied by Messrs. E. Dent and Co. The former has a cast-iron back which is firmly screwed to iron bolts cemented in the pier placed in the clock-room. The pendulum has the zinc and steel compensations originally designed for the transit of Venus expeditions. The clock was also supplied with a galvanic contact apparatus omitting one second each minute, for working a sympathetic dial in the transit-room, but as the contact-apparatus was found to interfere with the going of the standard-clock, its use was discontinued early in 1885, and the observations have since been made with a chronometer which is subsequently compared with the standard-clock.

The mean daily rates during ten-day periods of the standard clock are given in a table, and from the rates between January 1 and June 9 the following formula for the rate at t degrees Fahrenheit is deduced:—

$$r = + 1s.\cdot247 - 0s.\cdot033 (t - 70^\circ).$$

The clock stopped twice during the year, viz. on June 12 and August 23, each time during a thunderstorm. A difficulty was experienced in the attempt to determine separately the barometric coefficient, since the mean height of the barometer in Hong Kong falls regularly as the mean temperature rises, but it appeared to be insensible.

It should be noted, however, that the mean rates which Dr. Doberck publishes here suggest that the formula given above is only correct within certain limits. The clock would appear to be compensated for 80° or 85°; at least there seems to be no regular variation in its rate about these temperatures, the decline in the rate which accompanies the rise of temperature up to 80° showing a check or even a slight reversal about that point. Probably, however, the mean daily rates cannot be trusted to the degree of refinement to which they are here given. The number of transits observed is decidedly small, and the errors of the transit-instrument do not seem to have been very frequently or regularly determined during 1885. No information is given as to the degree of accordance of the daily rates actually observed.

The mean time clock is similar to the sidereal standard clock, and appears to go as well. It is furnished with galvanic contact springs, which are pressed every hour at the exact second, and send a current through a reversing commutator worked by one Léclanché cell, by means of which the current that drops the time ball at 1 p.m. is closed.

Some trouble has been experienced with the time ball. First the galvanic coil in the mean-time clock-case for setting the clock right before the ball is dropped, is not strong enough, as it takes nearly an hour and a half to correct an error of a second. The lock sent out with the

time ball, also, was not fit to drop the ball, the blow of the hammer failing to discharge the bolt, so that the hammer had also to be struck at the instant the current arrived from the clock. The coil was fused by lightning on June 12, and from that date until November 20, the ball was dropped by hand. Since November 22 a new lock has been fitted, which gives satisfaction.

The time-ball tower is erected on Tsim-sha-tsui Point, directly facing the shipping. It stands in front of the new police-station beside the mast for hoisting meteorological signals, at the foot of which the typhoon gun, pointed towards the city opposite, is placed. In the police boat-basin, at a short distance north-west of the tower, the small observatory is built. The time-ball tower is about half a mile distant from the observatory, with which it is connected by wire. The base of the tower is about 40 feet above sea-level, and the top of the ball-mast about 84 feet. On the ground-floor is a massive granite pier, which supports the entire apparatus. Dr. Doberck describes at considerable length the arrangements for dropping the ball, for breaking its fall, and for ascertaining that the fall has taken place at the proper instant, but they do not call for special remark. The accuracy of the time-ball signal at 1 o'clock depends, he says, practically upon the error of the standard clock being accurately determined. If the weather has permitted transit observations to be made the previous evening, the error of course will be pretty closely known; otherwise the regularity of the rate of the standard clock must be trusted to. A table of the errors of the time-ball in 1885 is given, showing that the mean probable error of the signal for each month is about 0·2s.

The time service is at present confined to the dropping of this ball, but there would be, Dr. Doberck points out, no difficulty in dropping any number of time-balls along the coast or distributing hourly time-signals to the principal public buildings, &c.

The observatory possesses three chronometers, the rates of which are here given. Of the three, two keep mean-time, and one keeps sidereal time, but one of the former is useful only as a hack watch.

The equatorial of the observatory is the Lee equatorial, described by Admiral Smyth in the "Speculum Hartwellianum" and the "Celestial Cycle." The great length of the polar axis renders the instrument unsteady and sensitive to every motion of the observer. A Maclean star spectroscope has been fitted to it. The object-glass appears to be still in good condition.

The meteor shower (the Andromedes) of November 27 was observed, and it was estimated that about 2000 meteors an hour were visible, most being small; none being brighter than the first magnitude, and only a few so bright. The radiant was determined to be at R.A. 27°, Decl. 40° N., but it was at least 3° in diameter.

THE RAINFALL OF THE CAPE COLONY

OBSERVATIONS of rainfall were begun in the colony about forty-five years ago, but until 1876 no general system of registration was in force; and, except in the case of the Royal Observatory and a few other stations, no continuous records were available. In 1876, however, Mr. John G. Gamble, M.A., M.Inst.C.E., the Hydraulic Engineer to the Colony, induced the Government to grant a sum of 100*l*. for the purpose of establishing rain-gauges throughout the country. This grant has been continued yearly since then, with the result that, although the sum is quite inadequate for the speedy erection of the number required, there are now 250 gauges from which monthly returns are obtained. A gauge is placed at every seat of magistracy, and private persons are also supplied with gauges free of charge on condition that they observe continuously for five years, and forward monthly returns to the Meteorological Commission at Cape Town. All the services rendered by the observers are gratuitous. The monthly returns are tabulated and printed together with other meteorological observations in a report by the Meteorological Commission, which is presented annually to the Colonial Legislature.

At the end of 1883 there were 75 stations at which records had been kept for at least five years. An appendix showing the average rainfall for each month of the year at these stations was published by the Meteorological Commission in their 1883 report, and in their report of the following year some diagrams plotted from these averages were included, which show more strikingly than figures the fluctuation of the rainfall from month to month.

That the observations begun ten years ago are beginning to bear good fruit is evident from the series of rainfall maps exhibited in the Court devoted to the Cape of Good Hope at the Colonial and Indian Exhibition. There are sixteen maps altogether, fourteen of which have been compiled by Mr. Gamble and two by Mr. W. B. Tripp, F.R.Met.Soc. One of those by Mr. Gamble shows the position of the gauges and the districts into which the colony has been divided for the purpose of rainfall registration; the others represent, by means of different colours, the general distribution of rainfall for each month of the year and for the whole year. The contours on the maps for the various months show differences of 1 inch in the rainfall, starting from a contour indicating the area where the fall is less than 0·5 inch. The contours on the map for the year indicate differences of 12 inches, beginning at 6 inches, and going up to 54 inches. The number of inches of rainfall at the various places is marked in figures.

Mr. Tripp's maps are intended to show the relation between the physical configuration of the country and its rainfall—one map representing contour-levels every 1000 feet up to 4000 feet, and the other representing the mean annual rainfall.

A casual examination of the various maps is sufficient to show that the conditions which determine the rainfall are not the same for the whole of South Africa. Thus in the south-west district of the Western Province the chief portion of the rain falls in the winter months, while in the Eastern Province, and in Natal and the Orange Free State, the greater portion falls in the summer, from October to March. On the southern seaboard of the Cape Colony the rainfall is irregularly distributed throughout the year, the greatest monthly fall at any place varying from one-ninth to one-eighth of the total.

A glance at Mr. Gamble's map showing the distribution in the year, shows that the north-west part of the colony is almost rainless. With the exception of the tract occupied by the Namaqualand Mountains, the average yearly fall in this desert is less than 6 inches; at Pella, a village on the Orange River, the rainfall for the year is 2½ inches, one-fifth of which falls in May. Some of the months at this place are rainless. Throughout the greater part of the colony the yearly rainfall varies from 6 to 18 inches, the smaller falls being characteristic of the regions in the interior, generally known as "The Karroo," from 2000 to 4000 feet above sea-level, and of a plateau nature; while the greater falls are found nearer the sea, and in the mountainous parts. In the south-west district, excluding the Cape Peninsula, and on the narrow strip of country on the south coast, between Swellendam and Port Elizabeth, the yearly rainfall ranges from 18 to 30 inches, except in the forests of George and Knysna, where it exceeds 40 inches. In the Cape Peninsula the rainfall varies from 25 inches at the Royal Observatory to 54 inches on the south-east side of Table Mountain. In the eastern districts of the colony, and in the neighbouring territories, where the main portion of the rain comes in summer, the fall averages from 18 to 30 inches,

with somewhat higher records from the Amatola forest region. There are doubtless many places in this great tract, notably in the Drackensberg, where the rainfall exceeds that shown on the maps, but there are no records to admit of the area being mapped.

With regard to the causes which determine the variation in the rainfall, Mr. Gamble has pointed out that this is due chiefly to the sea-currents and the prevailing winds. "Natal and the Eastern Province (of the Cape Colony) get their rains chiefly in summer, when the south-east trade wind blows," while "the western portion of the Western Province gets its rain mainly in winter with the north-west wind" (*Trans.* Philos. Society of South Africa). From whatever direction the rain may come, it seldom penetrates beyond the mountain-range which runs parallel to the coast. This barrier, as shown by Mr. Tripp's contour map, separates the elevated central plateau from the tract of lower country on the coast. During some of the summer months it would appear as if the south-east clouds were carried over parts of this barrier, but generally all the rainfall in the midland districts of the colony comes from thunder-showers of a very local character, heavy rain falling on one farm, while it is dry all round. It might be asked why, if the western portion of the Western Province gets its rain with a north-west wind, should the midlands not get their supply from the same source. To this Mr. Gamble answers: "We may note that the anti-trade of the Western Province comes apparently from a portion of the equatorial regions that is occupied by sea, while the north-west winds that blow in the Eastern Province, if they really keep their theoretical curvilinear path and are not interfered with by the height and temperature of the ground, come from a portion of the equator where there is land and consequently small evaporation."

As might be expected, the areas occupied by given rainfalls alter in position and size from month to month, but these fluctuations cannot well be described without the aid of maps. It may be noted, however, that in May, which marks the beginning of the wet season at Cape Town, the area over which the rainfall varies from 0·5 to 1·5 inch occupies nearly the whole of the colony. The maps for October to March are extremely interesting, as marking the gradual advance of the rains which come from the south-east. Concerning droughts and floods, Mr. Gamble has made the pregnant remark:—"It is frequently said that in such and such a year there was a drought in the colony; in another year, heavy floods in the colony. This way of speaking is incorrect, for, in consequence of the very distinct climates of the east and and west respectively, it is very rare that a drought occurs all over South Africa at the same time."

As the future prosperity of South Africa depends on irrigation, it is almost needless to point out the importance of the work done by Mr. Gamble. Considering the small outlay which has been incurred, the results are remarkable. Whether the work will in future be carried on in the same scientific spirit as it has been hitherto is somewhat doubtful in view of the backward tendency at present in course of development in the colony.

THOMAS STEWART

FERDINAND STOLICZKA

IN an interesting memoir, published by order of the Government of India, Mr. V. Ball gives a sketch of the life and work of Dr. F. Stoliczka, for many years Palæontologist to the Geological Survey of India. This memoir appears in connection with the publication of the scientific results of the second Yarkand mission, of which Stoliczka was Naturalist, and during the return journey of which he met his untimely end.

Born at Hochwald, in Moravia, in May 1838, Stoliczka obtained his early education at Prague, from whence he proceeded to Vienna, where he took the degree of a Doctor of Philosophy. To Prof. Suess he was indebted for his first regular training in geology, and he received the kindliest help in palæontology from Dr. Hörnes, who was for some years Director of the Austrian Imperial Mineralogical Cabinet, and was well known by his researches on the Mollusca of the Vienna Tertiary. He died in the prime of life, but not before he had seen the firstfruits of Stoliczka's labours on the Cretaceous fossils of India. Stoliczka's first contribution to science was made (1859) to the Vienna Academy of Science as a memoir on some fresh-water Mollusca from the Cretaceous formation of the North-Eastern Alps, and in 1861 he became one of the staff of the Austrian Geological Survey, of which Dr. Haidinger was then the chief. Here he had the fullest opportunities of working at his favourite pursuit, and well does he seem to have availed himself of them. There was a conscientious accuracy as well as an extensive knowledge of his subject displayed in Stoliczka's writings of this period that early marked him out for a brilliant career.

In the year 1862 he received the appointment of Assistant to the Geological Survey of India, and was present with Dr. Oldham, the Superintendent of the Survey, at the meeting of the British Association at Cambridge over which Prof. Huxley presided. There are many who may still remember his slight figure, and dark hair brushed back: in after days he became rather stout. At that time he knew but a few words of English, but very shortly afterwards we find him not only speaking and understanding English well, but actually writing notes in his journal in English.

On his arrival at Calcutta he at once commenced to work on the Cretaceous fossils of Southern India, and the splendid series of memoirs on these forms, of which Part I appeared in 1863, was not completed until ten years afterwards. These memoirs, in which as to the Belemnites and Nautilus he was assisted by Mr. Blanford, form a work of over 1400 pages, illustrated by 176 plates, a record in itself of a laborious life. The work of arranging and describing the fossils collected by others was, however, only a small portion of the work performed by Stoliczka. He threw himself with ardour into everything that pertained to the natural history of his adopted country, and there was scarcely a division of the animal kingdom that he had not a tolerable acquaintance with, and to the published records of which he did not add something—Mammalia, birds, reptiles, mollusks, Polyzoa, arachnids, Crustacea.

From time to time his work took him from the Museum workshops, and he visited now the North-Western Himalayas, and again the Andaman Islands, and portions of Burmah. In all and every place he visited he found something new and interesting, and by the numerous papers which he published as the result of his travels, one might almost follow him in his journeyings.

In 1873 it had been arranged that Stoliczka should go to Europe to take charge in part of the splendid collection of minerals and fossils sent to the Great Exhibition of Vienna from the Geological Survey of India, but he was tempted to go instead as one of the mission from the Government of India to the King of Yarkand and Kashgar. On May 17 he left Calcutta on a journey from which he never returned. Yarkand was reached on November 8. Early in October, and shortly before crossing the Sanju Pass (16,500 feet high), Stoliczka had been seriously ill from apparently a slight attack of spinal meningitis, from which, however, he rallied, and he seems to have enjoyed the three weeks' sojourn at Yarkand. On December 4 Kashgar was reached, but the formal presentation to the King of Her Britannic Majesty's letters did not take place till January 10, 1874. In February an excursion was made to Artish and Kalti Ailak, and on March 17 leave was

taken of the King, and the return journey to India commenced. Returning by Yarkand, the Kara-korum Pass was ascended on June 16, and Stoliczka seems to have suffered from the great height. On the 17th the last record appears in his journal. On the 18th the first symptoms of a new attack of spinal meningitis showed themselves, and, despite all the care of his devoted friends, he breathed his last on the afternoon of the 19th, some eleven marches from Leh, where he was buried beneath a willow-tree. The Government of India placed a suitable inscription over his grave, and other evidences of the esteem and regard in which his memory is held will be found in the Museums of Calcutta and Vienna. And now another, and this not the least, will be found in this too brief, but sympathetic, record of his life and labours, written by one who knew him well, and who was able to appreciate not only the scientific labours of his friend, but his honesty and loyalty. A detailed list of all the scientific papers and published letters of Stoliczka between 1859 and 1874 is appended to this memoir.

THE IRON AND STEEL INSTITUTE

THE summer meeting of this Institute was held on the 6th to the 8th inst., in London, under the presidency of Dr. John Percy, F.R.S. In his introductory remarks, the President made special reference to some of the papers about to be read. He was very pleased to see that the employment of chromium in the manufacture of steel was receiving attention. As far back as 1821 Bertheir, in the *Annales des Mines*, had shown that iron with 1 to 1·5 per cent. of chromium forged well, whilst it took a keen edge when ground, and had a very high tenacity.—Dr. Percy exhibited a portion of a broken ploughshare of American manufacture, which was formed of three metals, and seemed to be produced by casting steel on both sides of malleable iron. He drew attention to mitis metal, but refrained from offering any opinion on the subject, referring simply to the statements put forward that by the use of aluminium in its composition the melting-point was lowered, whilst, as the product was more liquid, it ran better, and sound castings were more easily produced. In speaking of Indian metallurgy, reference was made to the iron column at Delhi, the largest piece of forged iron in the world. The President next drew attention to the development of iron and steel-making in the United States, showing its rapid progress, and how enormously the capacity for production, both in that country and here, was in excess of the demand, as regarded blast-furnaces, Bessemer converters, and open-hearth furnaces. The address concluded with some remarks on diminished cost of production; to what a degree this has been carried, and the influence it has had on the labour market may be inferred from the circumstance that nowadays a single lace-making machine does the work formerly done by 2000 women, that wood-planing, which used to cost 12*s.* per square foot, is now done for 2*d.* or 3*d.*, that the manufacture of gold chains has been reduced from 30*s.* to 3*s.* 6*d.*, and that a gross of steel pens may now be procured for 4*d.* which used to cost 7*l.* Sir Henry Bessemer proposed a vote of thanks to Dr. Percy for his address, which was seconded by Mr. Adamson, the President-Elect.

The first paper read was that of Sir Frederick Abel, F.R.S., and Colonel Maitland, Superintendent of the Royal Gun Factories, Woolwich, on the erosion of gun-barrels by powder-products. This, in the author's opinion is due to a softening, if not fusing, effect exerted upon the surfaces of the metal by the high heat of the explosion, an increase of this softening or fusing effect by the chemical action of the sulphur at the high temperature produced, and the mechanical action of the rush of gases, vapours, and liquid products upon the softened or fused surfaces. There are two kinds of scoring or erosion: muzzle-loading scoring is due to the rush of powder-products over the top of the projectile through the clearance or windage, which has to be allowed for facility of ramming home the shot along the bore in a muzzle-loader; breach-loading scoring is produced by the rush of the powder products behind a shot, acting as a gas-tight plug, during and immediately after its passage through the gun. Evidently erosion will increase with the amount of the powder products, with the pressure in the bore, and with the duration of the time of action, and it is important to ascertain what material best resists erosion by powder products, or what treatment of the material is best calculated to increase its power of resistance to erosion. With this object in view experiments were made on thirteen rifled barrels, of different steels, of $2\frac{1}{4}$ inch bore, firing 100 rounds each with $10\frac{1}{4}$ lb. charges of pebble powder and 6 lb shot, fitted with service driving rings; these barrels were screwed into the mouth of the chamber of a 22 cwt. breech-loader. Gutta-percha impressions were taken after each batch of twenty-five rounds. During the preparation of the barrels specimens were cut in prolongation of the bores and tested mechanically, and the proportions of carbon, silicon, and manganese were determined in samples of the metal. The average pressure of the gas was 13 tons to the square inch. The results of the experiments are given in a table, but neither the chemical analysis of the metals nor the testing machine gave any assistance in accounting for the position of the barrels in the mean order of merit in which they were placed by five skilled and independent observers. Thus the worst and the worst but one were respectively the highest and nearly the lowest in carbon, the first, fifth, and tenth were very closely allied both in analysis and as tested by the machine, and it became evident that some agency, hitherto unsought for, dominated the results. Separate and independent investigations were made by the writers of the paper, the one instituting a chemical and the other a mechanical examination of the metals. A chromic solution capable of exerting a very slow solvent action upon the metals brought their structure into relief, and the extent of erosion was found to be more or less referable to the less or greater amount of mechanical treatment the metal had received, and to the consequent extent to which uniform fibrous structure had been developed. Experiments made on the metal as cast, and forged to twice to four times, and to eight times its length proved that the more steel was forged or worked the less it suffered from the eroding effect of powder gas. This was found to be the case both as regarded hard and soft metal. Several members took part in the discussion, notably Mr. Adamson, Sir Frederick Bramwell, Sir Henry Bessemer, and Mr. Frederick Siemens.

The next paper, which was taken as read, was an elaborate report of 137 pages in length by Messrs. P. C. Gilchrist and E. Riley, "On the Iron-making Resources of the British Colonies and India, as illustrated at the Colonial and Indian Exhibition." It would appear the reporters are of opinion that, so far as the exhibits are concerned, the iron and coal producing power of the Empire is rather undershown, as with a proper application of the materials at the disposal of our colonies and India, they should at all events be able to supply their own requirements.

The next papers read were: "On some Early Forms of Bessemer Converters," by Sir Henry Bessemer, F.R.S., and "On Modifications of Bessemer Converters for Small Charges," by John Hardisty. The first of these contains descriptions of the different forms of converters selected by the author as typical of the whole, and which embrace the main features of ten several forms of apparatus which he has from time to time designed for the conversion of crude iron into steel. It was written with the double object of letting those who are seeking to improve the

process know what has already been done; while the general public ought not to remain ignorant of what legitimately belongs to them, and which, after the ample reward he has received for his inventions, the author desires they should enjoy without any restrictions. The author of the second paper holds that the making of steel in small quantities is a step in the wrong direction, because the steel cannot be made so cheaply; but, as he points out, it is to the interest of owners of small blast plant to possess the means of converting their product into steel, and of ironworkers who cannot find work for their puddling furnaces to make steel enough to keep their machinery at work rather than be dependent on larger firms for a supply of ingots. An American steel-maker in the discussion drew attention to the circumstance that in the United States, when the rail trade was brisk, it was impossible for the smaller works to obtain Bessemer ingots at all, and that they had to introduce small plant for self-preservation. From the statement of opinion it was evident that there was necessity for the original Bessemer converters and the smaller modified forms.

Mr. Frederick Siemens's paper on combustion with special reference to practical requirements draws attention to the means necessary for adoption to insure perfect combustion. The gases must be supplied in the exact chemical proportion in which they are required for combustion; they must be brought together in such a manner that the different molecules which have to enter into combination may readily do so, whilst every thing must be avoided which interferes with the motion of the gases while combustion is proceeding.

The author enters in detail on the way in which gases should be brought together, he explains that the Bunsen burner, though theoretically perfect, cannot be advantageously carried out in furnaces, as the flame of a Bunsen burner being almost non-luminous owing to free carbon not being liberated during combustion, has but little radiating power, and must in consequence transmit its heat by direct contact only. As the gases cannot generally be mixed before combustion, it is a matter of great importance how they are brought together when combustion commences, a mean being necessary between a too intimate mixture, producing a short flame having great heating but little radiating power, and an imperfect mixture, which does not allow of combination properly taking place. The third means necessary is the one to which the author has frequently drawn special attention, because neither the employment of gases in proper proportion, nor their proper mixture is sufficient to insure perfect combustion *if the disturbing influences of surfaces is allowed to interfere to prevent combustion, or to dissociate particles of gas already combined.* In the author's view the dissociation caused by hot surfaces is of various kinds, and takes place at different temperatures. At a comparatively low temperature, dissociation of hydrocarbons takes place, the carbon being liberated in the solid form as soot. At a moderately high temperature carbonic oxide is dissociated into solid carbon and carbonic acid gas; at a higher temperature the products of combustion begin to dissociate, steam splitting up into hydrogen and oxygen, and lastly, at a still higher temperature, depending upon the kind of surface with which the products of combustion come into contact, carbonic acid splits up into solid carbon and oxygen. From this it will be seen that dissociation has the effect of setting carbon free, and to its influence the formation of smoke is largely due.

The author then proceeded to show that smoke within a furnace chamber is caused by flame in the first instance touching surfaces which then become enveloped in a dense cloud of dissociated carbon, which prevents the heat rays from reaching them. The author illustrated his remarks by means of a gas-burner proposed to be used instead of the English fire-place, by the use of which it is stated that heat is much more uniformly distributed throughout a room. The flame was intensely bright and hot, due as explained to its being fed with hot air, and working with free development of flame that is entirely out of contact with any surfaces. The gas stove afforded considerable interest to the members, and the author by special request explained its mode of action.

The papers read on the last day of the meeting were two by Mr. F. Gautier, of Paris, on the casting of chains in solid steel, and on silicon in foundry iron. Hitherto chains have been made of wrought iron, the difficulty in the various processes of manufacture being the difficulty of securing a good weld; this, according to the author, is now overcome by a process of Messrs. Joubert and Leger, of Lyons, which combines chilled casting and instantaneous removal from the moulds. In the second paper the writer refers to the advantage of silicon in producing homogeneous steel and pig iron castings and improving foundry pig; he also drew attention to the introduction of ferrosilicon in French foundry practice. The author's views were in general supported by the members in discussion. Mr. F. W. Harbord's paper, "On the Elimination of Silicon, Phosphorus, &c., in the Basic Open-hearth Process," gave evidence that soft steel of the very finest quality could be produced from inferior material by this process, whilst the conditions of working in the Siemens furnace are peculiarly favourable to its production. Surgeon-Major Hendley's paper, "On the Process employed in Casting Brass Chains at Jeypore, Rajputana," was contributed by Mr. C. Purdon Clarke, and illustrated by samples. The papers on "Chrome Steel," by Mr. Brustlem, and on "American Blast Furnace Practice," by Mr. F. W. Gordon, Philadelphia, were put off to the next meeting.

NOTES

We regret to learn that Baron von Müller retires from the directorship of the Melbourne Botanic Gardens in June next.

The death is announced of M. Dubosc, a Paris optician, who assisted M. Léon Foucault in all his constructions, and especially in the organisation of his automatic electric lamp.

The Laboratoire d'Électricité created with the surplus of the Electrical Exhibition of 1881, held in the Palais de l'Industrie, will be erected on the site of the old Collège Rollin, on ground granted by the City of Paris. It will be open to electricians of every nation, and governed by the International Society of Electricians.

An ordinary General Meeting of the Institution of Mechanical Engineers will be held in the Yorkshire College, Leeds, on Monday, October 18, by invitation of the College authorities, in celebration of the opening of the Engineering Department of the College. The following papers will be read and discussed, as far as time permits:—"On Triple-Expansion Marine Engines," by the late Mr. Robert Wyllie, of Hartlepool; "Notes on the Pumping Engines at the Lincoln Water-Works," by Mr. Henry Teague, of Lincoln; "Description of a Portable Hydraulic Drilling Machine," by M. Marc Berrier-Fontaine, of Toulon.

The Commission of the French Budget having adopted without reduction all the proposals of the Government for the Algerian provinces, the construction of the large instruments for Bouzareah Observatory will be continued, and inspection of the heavens will be conducted on a large scale at Algiers. An observer connected with the Trocadero Observatory has been appointed to assist M. Trépied, and left Paris last week for his destination.

The photographic method has been established at the Algiers Observatory for the sun. Nine times out of ten the operation has been successful.

THE Duc d'Aumale has bequeathed to the Institute of France in perpetuity the mansion and domain of Chantilly, with its museum and all its other contents, to be preserved and maintained for the benefit of the French nation. This munificent gift is fettered by no conditions beyond those necessary for carrying out the main purpose of the testator. The value of the gift is estimated at thirty millions of francs, or nearly a million and a quarter sterling, and the income for maintaining it at 20,000*l.* per annum.

SOME time since, Herr Paul von Ritter, of Basle, gave the sum of 300,000 marks for the furtherance of scientific inquiry on the basis of the Darwinian theory. It has now been decided to employ half the interest in the maintenance of a "Ritter Professorship of Philogeny." The chair is to be filled by Dr. Arnold Lang, formerly scholar and assistant of Prof. Haeckel at Jena. Dr. Lang has for several years taken part in the work of the Zoological Station at Naples. The other half of the interest will be expended in grants for scientific travel, and in furnishing improved means of instruction in zoology at this University. Herr von Ritter has been made Doctor of Philosophy *honoris causâ.*

SINCE the end of 1883, regular observations of atmospheric electricity have been made at the Odessa Meteorological Observatory, and M. Klossofsky shows by the graphic method (*La Nature*) how there is an intimate relation between the variations of atmospheric pressure, and those of electric potential. Cyclonic movements of the atmosphere find a faithful echo in the indications of the electrometer, though sometimes mist, smoke, dust, and atmospheric precipitates may for a time mask the correspondence.

IN the course of a review in the *Chinese Recorder* of a new Chinese geometry by Dr. Mateer, Dr. Martin, the head of the Foreign Language College at Pekin, states that the first translation of Euclid into Chinese was made by the illustrious Father Ricci, "the apostle at once of religion and science." In time the paramount influence of Euclid grew into something like a bondage in the east as well as in the west. In the west a wholesome revolt took place long ago, but in China Euclid "has reigned with undisputed sway for three centuries, and nothing has been done even in the way of simplification until the work of Dr. Mateer. It is a strange fact that Ricci's Euclid was left standing through all these ages in the condition of a truncated pyramid. Only six books were translated by the great Jesuit, and the remaining nine were supplied about thirty years ago by Mr. A. Wylie, aided by Prof. Li Shenlon." Mr. Wylie subsequently translated Loomis's "Analytical Geometry and Differential Calculus"; but, says Dr. Martin, he would have done better to have commenced his mathematical textbooks by a version of Loomis's "Geometry," which, following the footsteps of Legendre, presents the whole subject in a compact and easily intelligible form. The translation of the Chinese titte of the older book is "First Book in the Science of Quantity"; that of Dr. Mateer's is "The Science of Form." A Chinese mathematician's view of the new work is given by Dr. Martin in the following words:—"This book presents the principles of geometry in a more concise form than Euclid, and omits nothing of importance that is found in Euclid. Besides the chapter on the three round bodies, there are throughout many excellent theories that were unknown to Euclid, especially those relating to spherical triangles, so essential to the study of astronomy." The price of the two volumes, it may be added, is about 2*s.* 3*d.*

THE number of the *Folk-Lore Journal* (vol. iv. part 4) just published, contains the first instalment of a paper by Capt. A. C. Temple, which promises to be the most important work yet published on the folk-lore of North-Western India. The writer has made it a practice to collect all the popular works published in the Punjaub relating to history, folk-lore, and religion. He has now about 350 of these in Arabic, Persian, Urdu, Hindi, Punjaubi, Pushtoo, and Sanscrit. It faithfully represents the current popular literature of the day in the Punjaub. Capt. Temple has had abstracts of the books prepared, and twenty-eight of these are published in the present paper. In the somewhat distant future when the whole 350 are published, few regions will have had their folk-lore so thoroughly investigated as the Punjaub.

ACCORDING to *Die Natur* a remarkable collection of minerals exists in the cellars of the Academia San Fernando at Madrid. It is contained in a number of boxes which have filled the cellars for about 200 years, and which may remain there as long again unless some better fortune befalls them than that which has attended them in the past. They come down from the golden age of Spanish domination in South America and in Mexico, when the mines of these regions made them the El Dorado of the globe. No one knows exactly the contents of the boxes, but they are believed to contain the rarest objects, although the scientific importance of collections was but little appreciated in the days when this one was made. It appears also that collections made by Humboldt during his travels in America, and handed over by him as a kind of scientific tribute to the Spanish Government, are in the same Academy "locked up since 1804 in a press, untouched." With respect to the famous skeleton of the *Megatherium americanum*, Cuv., found by the Marquis de Loreto on the banks of the Rio Luxon near Buenos Ayres in 1778, which is in the Museum of the Academy, its present state is described by the brothers Fraas of Stuttgart in their letters from the south of France and Spain, just published under the title of "Aus dem Süden," as being one of the utmost confusion. The bones are bored for mounting, but they are "completed and restored" to the verge of the impossible. The bones are placed in absurd positions, and parts which were inconvenient to the mounter are put aside altogether. The writers ask what the state of instruction in natural history must be in an Academy where such things are possible.

WE have never heard an adequate explanation of the extraordinary delay which takes place in the issue of the Annual Reports of the Japanese Ministry of Education. They are as a rule three years behind time. That for 1882 has only just been published. They contain a considerable number of statistics, but this alone would not account for the delay, for the publications of, say, the Japanese Meteorological Observatory contain far more and more complicated tables, yet the latter appear in reasonable time. It is very difficult to feel any interest in an annual report of the year 1882 at this date; conditions have altered, the circumstances are different, the inspector's report for 1885 may show energy and success where those of 1882 had to reveal apathy and ignorance. The Tokio University, for example, has been wholly remodelled, and one reads with very languid interest now that in 1882 there were such and such departments, so many graduates, and the like. The details in the report, especially those relating to students abroad, to the position of libraries and museums, their utility to and appreciation by the public, would be of interest and well worth quotation, or at least a short summary, if they were those of last year instead of those of four years ago. These reports may perhaps be of use to any one who undertakes to write a history of education in Japan; for any practical present use they are they might as well remain unpublished in the Archives of the Education Department in Tokio. We can perceive nothing in the nature of things, or in the design or details of the reports to prevent them being produced regularly in the first half of the year succeeding that to which they refer.

In a very interesting paper in the new number of the *Asiatic Quarterly Review*, Miss E. M. Clerke, writing on "Arabic Analogies in Western Speech," says that whole classes of astronomical, astrological, and generally scientific terms are a standing memorial to the debt of culture Europe owes to the East. Logarithm is a corruption of *el-jowarzeem*, and algebra of *el-jabr wa'lmukábala*, literally, the integration and comparison. Alembic is *el-anbik*, a retort, whence the Italian *lambiccare*, to distil; and nearly all the terms used in alchemy denote its Oriental origin. Star-names come from the same source: Algol is *el-ghol*, the ghoul; and Vega, a fragment of *nasser-el-waga*, the falling eagle. Most precious stones and minerals, as sapphire, emerald, bezoar, jasper, amber, antimony, are transparent disguises of Arabic originals; jewel itself is from *jouhour*. Similarly the names of poisons and remedies, as well as maladies, come from Arabia: thus arsenic is *ez-zernikh;* massage, the fashionable cure by friction, is from *mass*, to handle, and leprosy is an obvious corruption of *el-abras*. Again, such words as spinach, endive, chicory, saffron, arrowroot, cotton, hemp, carraway, cummin, and aloe are obvious derivatives from Arabic. The names of many flowers come from Arabia, by adoption from Persian, also fruits, as lemon and orange. Carat is an Arabic weight. Monsoon comes from *mousem*, a fixed time, and sirocco and simoom. These and a hundred others given by Miss Clerke "go to prove that the world is one vast commonwealth of ideas, most widely shared by the classes least conscious of their indebtedness to foreign influence."

Father Dechevrens, of the Siccawei Observatory near Shanghai, writing on a violent typhoon which visited that district on August 14, doing considerable damage, says that it was remarkable by the long persistency of the low pressures that continued from 3 a.m. on the 14th to 5 a.m. on the 18th, that is, ninety-three hours, during the whole of which time the wind blew hard, and during the two last days the rainfall rose from 6 inches to 12. He says this is a singular and very rare phenomenon, and to explain it he follows the typhoon all along its course. Like the typhoon of the same date in 1881, it came from the open sea. On the 11th the barometer at Manilla caused suspicion of a storm to the north-east of Luzon and east of Formosa. The Loochoo Islands must have been passed on the afternoon of the 13th, and at noon on the 14th it reached the coast of China about Wenchow. Having got to the mainland, the storm proceeded for some time to the west through the province of Kiangsi, and then was divided. One part recurved to the south-west towards Kwangsi and Tonquin, and is easily followed by observations made at Amoy and Hong Kong; the other part of the depression turned round to the north and got nearer to the Yang-tse River. On the morning of the 18th an entire change took place in the atmospheric conditions. The second depression was in its turn divided, and while the portion higher in latitude formed itself into a distinct storm and got away to the north, the other part approached Shanghai and put back to sea through the mouth of the Yang-tse. When Shanghai was placed between the two depressions, the air, not knowing, as it were, towards which of them to flow, got rapidly calm. While the two centres were thus getting away in opposite directions, the Siccawei barometer rose without any strong wind blowing. This, concludes Father Dechevrens, is a new phase of this singular typhoon, the centre of which passed very close to Shanghai without giving birth to any gale, except the one that had preceded the division and the departure. It is to be hoped that the learned writer may be able to give this typhoon, with the peculiarities here noted, the same detailed and thorough study that he gave that of 1881. In the latter instance he gave what may be called the life-history of a storm from its birth in the China Seas, almost to its dissipation far in the interior of he continent of Asia.

The luminosity of insects has been lately studied in a very careful manner by Dr. Dubois, one of M. Bert's students. The animal selected was the American *cucujo*, or *Pyrophorus noctilucus*. It has three luminous organs—two prothoracic and one ventral. Dr. Dubois opposes the view that the light results from direct oxidation of the substance of the luminous organs, by oxygen of the air coming through the tracheæ. In pure oxygen the luminosity is the same as in air, and it is the same in pressures under one atmosphere. Nor does compressed oxygen affect it, and this gas cannot restore the light when extinct in organs which yet respond to mechanical agents or electricity, even when the pressure is raised to four atmospheres. The prothoracic plates give a good illumination in front, laterally, and above, and serve when the insect walks in the dark; when it flies or swims, its fine abdominal lantern is unmasked (and the abdomen raised) throwing downwards an intense light with much greater range. The insect seems to be guided by its own light. If the prothoracic apparatus is quenched on one side with a little black wax, the cucujo walks in a curve, turning towards the side of the light. If both sides are quenched, the insect walks hesitatingly and irregularly, feeling the ground with its antennæ, and soon stops. The light of the cucujo gives a pretty long spectrum from the red to the first blue rays; when the light diminishes, this shortens somewhat on the side of the blue, but more on the other side. The maximum is about wave-length 528 μ 56 (as in the solar spectrum). The light is more green than that of *Lampyris noctiluca*. It is capable of photography, but does not develop chlorophyll. The prothoracic organs of six insects did not set a radiometer in motion, but they affected a Melloni pile slightly. No distinct electric action could be traced in the organs. Separated from the body, the organs are still brilliant. If the insect is deprived of water, it ceases to produce light; and it recovers the power when plunged in water. The eggs may be dried to the extreme limit, at ordinary temperature, without losing their light-yielding power; put in water after eight days even, they become luminous again. Further, if the luminous organs are dried *in vacuo*, and pulverised in a mortar, a little water (even if freed from gas by boiling) makes the mass luminous throughout. Dr. Dubois finds the photogenic substance to be an albuminoid, soluble in water and coagulable by heat; it enters into conflict with another substance, of the diastase group, and part of the energy thus liberated appears as light.

Some experiments lately brought before the Paris Academy by M. Luvini, combine with those of other observers (he considers) in warranting the conclusion that "gases and vapours, under any pressure, and at all temperatures, are perfect insulators, and cannot be electrified through friction, either with one another, or with solid or liquid substances."

The *Giornale d'Agricoltura e Commercio* for August reports the discovery in West Africa of a new variety of coffee-plant, whose berry appears greatly to resemble that of Arabia in appearance and flavour. It grows, however, not on a shrub but on a tree nearly 7 feet high, which develops rapidly and yields an abundant crop. Arrangements are already being made for introducing its cultivation in favourable localities.

The additions to the Zoological Society's Gardens during the past week include a Brown Capuchin (*Cebus fatuellus* ♀) from Guiana, presented by Messrs. Kühner, Hendschel, and Co.; a Macaque Monkey (*Macacus cynomolgus* ♀) from India, presented by the Countess de Geloes; a Yellow-footed Rock Kangaroo (*Petrogale xanthopus* ♀) from South Australia, presented by Mr. G. Langborne, Chief Officer s.s. *Rome;* a Common Squirrel (*Sciurus vulgaris*), British, presented by Miss Gertrude Hudson; two Lanner Falcons (*Falco lanarius*) from Eastern Europe, presented by the Baron D'Epremesnil; a Blue and Yellow Macaw (*Ara ararauna*) from South America, presented

by Mrs. George Quish; a Gannet (*Sula bassana*), British, presented by Mr. J. H. Gurney, F.Z.S.; two Common Chameleons (*Chamæleon vulgaris*) from North Africa, presented respectively by Mr. Charles T. Port, F.Z.S., and Mr. T. H. Carlton Levick; a Common Viper (*Vipera berus*), British, presented by Mr. W. H. B. Pain; a Porto Rico Pigeon (*Columba corensis*), a Triangular-spotted Pigeon (*Columba guinea*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN

M. THOLLON'S MAP OF THE SOLAR SPECTRUM.—M. Thollon, in the *Bulletin Astronomique* for July, gives some interesting details concerning the great map of the solar spectrum which he presented to the Paris Academy of Sciences about a year ago. He had completed an earlier design in 1879, but the positions of the lines in it had not been determined with the precision he desired. He therefore resolved to go over the work again, and to make a chart which should represent the positions, breadths, and relative intensities of the lines as faithfully as possible. The work has required four years of continuous toil to carry it from A to *b*, at which point M. Thollon now leaves it. M. Trépied proposes to carry it on to the violet. M. Thollon's map shows the spectrum under four different aspects: as seen when the sun is 10° high, and the air contains but little water-vapour; then as with the sun at 30° of altitude, first with the air saturated with water-vapour, and next when the air is very dry; and, lastly, the solar spectrum as it would be seen outside our atmosphere. It is therefore easy to see which lines are truly solar, which due to water-vapour in our atmosphere, and which to dry air. M. Thollon finds the dry-air lines limited to the great groups A, B, and α, which M. Egoroff ascribes to oxygen. Besides the water lines, which are arranged in seven groups, M. Thollon on a single occasion observed a vast number of telluric lines between α and D, the special origin of which he was not able to determine.

The measures were made with a very fine glass pointer, which allowed a bisection of a line to be made with great exactness, the probable error of an observation being less than 1/700 of the interval between the D lines. The breadth of a line was determined by observing at what distance from its extreme point, the glass pointer was equal to it in breadth. The intensity of the lines were estimated by eye. The map, which will be published in the *Annales de l'Observatoire de Nice*, is more than 33 feet in length, and embraces more than a third of the visible spectrum. From the scale on which it is drawn, the number of lines—about 3200—which it contains, the precision of the measures, and the fullness of the information given concerning the telluric lines, it will be, that which its author has striven to make it, the fullest and most perfect chart of the spectrum yet published. One of the chief purposes which it will serve will be to afford information as to the occurrence of changes in the spectrum, and M. Thollon shows by a diagram of the spectrum between B and C that we have strong reason to suspect that several lines have greatly altered in intensity since the date of Ångström's famous chart.

COMET FINLAY.—Mr. Finlay, of the Cape of Good Hope Observatory, discovered a comet on September 26. It appears to be probably identical with Comet 1844 I., its elements being given by Dr. Holetschek as follows:—

T = 1886 Nov. 22·6821 Berlin Mean Time.

$$\left.\begin{aligned} \pi - \Omega &= 299^\circ\ 14'\ 21'' \\ \Omega &= 48\ \ 35\ \ 55 \\ i &= 3\ \ 23\ \ \ 0 \end{aligned}\right\}\ \text{Mean Eq. } 1886{\cdot}0.$$

$$\log q = 0{\cdot}08793$$

Ephemeris for Berlin Midnight

1886	R.A. h. m. s.	Decl. ° ′	Log Δ	Log *r*	Brightness
Oct. 19	18 8 10	26 40·2 S.	0·1442	0·1249	1·37
23	18 21 52	26 33·9	0·1410	0·1173	1·44

31	18 51 6	26 4·7 S.	0·1347	0·1044	1·57

The brightness on September 26 is taken as unity.

NEW MINOR PLANET.—A new minor planet, No. 260, was discovered by Herr Palisa at Vienna on October 3.

NEW COMET.—A new comet was discovered by Mr. E. E. Barnard on October 4. It was independently observed by Dr. Hartwig on the following night. October 5, 16h. 2m. G.M.T., R.A. 10h. 37m. 24s.; Decl. 1° 3′ N. It is described as bright and round. Daily motion + 1·5s. in R.A., and + 3′ in Decl.

THE PULKOWA OBSERVATORY.—M. Struve has issued his Annual Report for the year ending May 25, 1886. During the year the fundamental determinations of star places for 1885·0 were regularly persevered in with the great transit instrument and the vertical circle. With the former Herr Wagner and his assistants, Wittram and Harzer, observed 4785 transits. With the exception of 110 observations of the sun these refer exclusively to the 383 Pulkowa fundamental stars. With the vertical circle Herr Nyrén obtained 739 complete observations, including 105 observations of the sun. The fundamental declination determinations for 1885 would be almost completed, had not Herr Nyrén wished to repeat the observations with a reversion-prism eye-piece attached to the instrument in order to investigate certain systematic discordances. Herr Romberg, observing with the meridian-circle, obtained during the year 4359 observations, chiefly of stars with large proper motion, comet stars, &c. The great 30-inch refractor has been intrusted to Hermann Struve, and has been employed in observing the fainter double stars of Burnham's catalogues, the satellites of Mars, Saturn, and Neptune, the Maja nebula (discovered photographically at Paris), and *Nova* Andromedæ, which was easily visible on January 27. M. Struve speaks in terms of the highest approval of the instrument, both as regards its optical power and as regards the mounting, the movement of the dome, &c. The 15-inch refractor has been used by H. Struve for obtaining micrometer measures of the brighter satellites of Saturn. He has obtained 42 comparisons of Japetus with Titan, 40 of Titan with Rhea, and 23 of Rhea with Dione. Herr Backlund has continued in charge of the 4-inch heliometer, and has measured with it the relative positions of Jupiter's satellites, for a determination of the mass of Jupiter, and of the orbits of the satellites. He has also undertaken a series of measures to determine the parallax of Bradley 3077, which has a large proper motion. In the physical department of the Observatory Herr Hasselberg, using a Steinheil objective of 50 mm. aperture and 1·5 m. focal length, in combination with two bisulphide of carbon prisms, has succeeded in obtaining excellent photographic images of the solar spectrum. Between wave-lengths 4000 to 4227 on Ångström's scale, he was able to count some 650 lines, whereas Vogel's map gives but 450 in the same space. During the course of the year 140 sun pictures were taken on 110 days.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1886 *OCTOBER* 17–23

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on October 17

Sun rises, 6h. 29m.; souths, 11h. 45m. 24·2s.; sets, 17h. 2m.; decl. on meridian, 9° 20′ S.: Sidereal Time at Sunset, 18h. 46m.

Moon (at Last Quarter on October 20) rises, 19h. 15m.*; souths, 2h. 55m.; sets, 10h. 42m.; decl. on meridian, 16° 55′ N.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′
Mercury ...	7 46 ...	12 34 ...	17 22 ...	14 33 S.
Venus	5 18 ...	11 4 ...	16 50 ...	3 32 S.
Mars	10 45 ...	14 43 ...	18 41 ...	22 45 S.
Jupiter... ...	5 52 ...	11 25 ...	16 58 ...	6 3 S.
Saturn	21 51* ...	5 53 ...	13 55 ...	21 19 N.

* Indicates that the rising is that of the preceding evening.

Occultations of Stars by the Moon (visible at Greenwich)

Meteor Notes

There are a large number of active radiants visible during the present week, the chief shower being the *Orionids*, R.A. 90°, Decl. 15° N. Other radiants are that of the *Arietids*, R.A. 31°, Decl. 9° N.; near ψ Aurigæ, R.A. 78°, Decl. 32° N.; that of the *Gemellids*, R.A. 108°, Decl. 24° N.; near μ Leonis, R.A. 143°, Decl. 28° N.; and near Vega, R.A. 283°, Decl. 43° N. October 18 is a fireball date.

THE NEW ELEMENT, GERMANIUM[1]

SOME months ago Dr. Clemens Winkler announced the discovery of a new element which he named germanium, a preliminary account of which has already appeared in these columns. Dr. Winkler has since been able to make a more systematic examination of the subject, and he now describes in detail the preparation and properties of the new element and also of a number of its compounds. The view he first held, that germanium occupied a position in the periodic system intermediate between antimony and bismuth, he now shows to be untenable, there being now no doubt that it is the *ekasilicium* of Mendelejeff prophesied fifteen years ago. This latter view was, in fact, expressed by Richter, Mendelejeff, and Lothar Meyer shortly after the discovery of germanium.

The new element occurs, as previously stated, in the recently-discovered mineral, argyrodite. Its isolation is, however, difficult, especially from the presence of arsenic and antimony in minerals which accompany argyrodite. The formula assigned to the latter mineral is $3Ag_2S,GeS_2$.

The following is the best method for separating the germanium. The finely-powdered mineral is intimately mixed with an equal weight of soda and sulphur, and the whole submitted to the action of a moderate red heat in a Hessian crucible. The product is powdered whilst still warm, and repeatedly boiled with water; the aqueous extract is slightly acidulated with sulphuric acid, and the precipitated sulphides of arsenic and antimony allowed to settle. On then adding a considerable excess of hydrochloric acid, the germanium sulphide is thrown down as a white voluminous precipitate; this is gently roasted, then heated with concentrated nitric acid, and finally ignited. The germanium oxide obtained may be reduced by ignition in hydrogen.

Germanium has a melting-point apparently somewhat lower than that of silver—that is, about 900°—and at a temperature a little higher than this it appears to volatilise. It crystallises in octahedra, is extremely brittle, has a perfect metallic lustre, and a grayish-white colour; its specific gravity is 5·469 at 20°·4. It is insoluble in hydrochloric acid, is readily dissolved by aqua regia, is converted into a white oxide by nitric acid, and into a soluble sulphate by concentrated sulphuric acid.

Determinations of the atomic weight of germanium were made by estimating the percentage of chlorine in the chloride, $GeCl_4$, and the number 72·32 was obtained as the mean of four experiments, this number agreeing closely with the atomic weight of Mendelejeff's ekasilicium.

The specific heat of the new element has been determined by Nilson and Pettersson, at temperatures between 100° and 440°, with the following results:—

[1] Clemens Winkler, *Journal f. prakt. Chemie*, 1886, pp. 177-229.

	1	2	3	4
Specific heat	0·0737	0·0772	0·0768	0·0757
Atomic heat	5·33	5·58	5·55	5·47

Compounds of Germanium.—Oxides: There are two oxides of germanium, namely, GeO and GeO_2. The former is obtained in the hydrated condition by heating the corresponding chloride ($GeCl_2$) with sodium carbonate solution; on heating the precipitate in a current of carbonic anhydride, the water is expelled and the grayish-black oxide, GeO, remains. The higher oxide is obtained by burning germanium in oxygen, or by decomposing the chloride, $GeCl_4$, by water; it forms a dense white powder slightly soluble in water, possesses both basic and acid properties, the latter being, however, the more pronounced. *Sulphides:* Two of these are likewise known, corresponding to the oxides. The lower sulphide, GeS, is obtained from the disulphide either by heating it with an excess of germanium in a current of carbonic anhydride, or by gently igniting it in a current of hydrogen; it forms beautiful thin plates of almost metallic lustre and having a gray-black colour. Germanium disulphide, GeS_2, is obtained by precipitating a solution of the dioxide by sulphuretted hydrogen with the addition of a considerable excess of a mineral acid; it is then thrown down as a bulky white precipitate which is very appreciably soluble in water. *Chlorides:* The dichloride, $GeCl_2$, is formed when hydrochloric acid gas is passed over heated pulverulent germanium or its sulphide; it is a thin colourless liquid, which fumes strongly on exposure to the air. The tetrachloride, $GeCl_4$, is produced by burning germanium in chlorine, or by distilling a mixture of germanium with mercuric chloride; it is a thin colourless liquid boiling at 86° C. and fuming in the air; its specific gravity at 18° is 1·887. *Iodide:* A tetriodide, GeI_4, only is known, and is best obtained by heating germanium in iodine vapour; it forms a yellow powder, melts at 144°, and boils between 350° and 400°.

AUSTRALASIA

THE following have been quite recently received from Australasia:—

Transactions and Proceedings of the New Zealand Institute for 1885, vol. xviii. (first of new series) (Wellington, May 1886). This volume commences a new series of these well-known *Transactions*, in which, "for convenience and economy" the size of the page has been reduced from the handsome royal octavo to a demy octavo size. The volume contains over 450 pages, and some 17 plates. Among the more important contributions which are printed in the *Transactions* may be noted the following:—*Miscellaneous:* E. Tregear, the Maori in Asia.—Dr. J. Haast, stone weapons of the Moriori and the Maori.—Rev. S. W. Baker, new volcano in the Friendly Islands.—*Zoology:* T. Jeffery Parker, skeleton of Notornis.—T. White, feathers of two species of Moa.—A. Reischek, numerous papers on New Zealand birds.—W. Colenso, on the bones of a new species of Sphenodon.—W. W. Smith, on the habits of *Ocydromus australis*.—J. W. Kirk, on a new species of Argonauta.—Geo. M. Thomson and Chas. Chilton, critical list of New Zealand Crustacea Malacostraca.—E. Meyrick, New Zealand Micro-Lepidoptera (Tineina, Pars.).—A. T. Urquhart, on the spiders of New Zealand (many new species described and figured).—J. W. Kirk, on some species of Vorticella from Wellington describes thirteen species, of which two are given as new, and figured.—*Botany:* W. Colenso, on some newly-discovered cryptogamic plants of New Zealand, describes some fifty-nine species; two ferns, fourteen mosses, and forty-three Hepaticæ, and hints that it may be the last lot of novelties that, owing to age, he may himself collect and describe.—On some new or rare native plants, chiefly phanerogams; on *Clianthus puniceus*, Sol.—D. Petrie, on new species of native plants.—R. M. Lang, on classification of Algæ, and on the Fucoids of Banks Peninsula.—T. F. Cheeseman, three new species of Coprosma.—T. Kirk, additions to the flora of Nelson.—*Geology:* Capt. F. W. Hutton, the geology of Scinde Island; new Tertiary shells; the Wanganui system, with a catalogue of the Mollusca.—A. McKay, on the age of the Napier limestone.—*Astronomy:* Notes on the total eclipse of the sun of September 9, 1885, being a digest of many communications.—*Chemistry:* W. Skey, on a new mineral (awaruite) from Barn Bay.—W. S. Hamilton, on platinum crystals in the ironsands of Orepuki Goldfield.

Proceedings of the Linnean Society of New South Wales, vol. x. part 4, with 18 plates (Sydney, April 1886).—Dr. R. von

Lendenfeld, studies on Sponges: (1) the vestibule of *Dendrilla cavernosa*, sp.n.; (2) on *Raphyrus luxonii*, a new gigantic species from Port Jackson; (3) *Halme tingens*; (4) two cases of mimicry in Sponges (plates 39-43).—On recent changes in the forest flora of the interior of New South Wales; notes how the Pine Scrub (Callitris) rapidly supersedes the angiospermatous trees. The larva of a beetle (*Diadoscus erythrurus*) in part keeps the pine in check; drought seems favourable to the development of the beetle, or at least, by affecting the vegetation of the pine, enable its ravages to be more felt.—On the Australian fresh-water Rhizopoda.—On an Alga forming a pseudomorph of a siliceous Sponge.—On the dorsal papillæ of Onchidium.—Fourth addendum to the Australian Hydromedusæ.—E. P. Ramsay and J. Douglas-Ogilby, descriptions of many new or rare fishes.—George Masters, catalogue of the described Coleoptera of Australia, part 2.—N. de Miklouho-Maclay and Wm. Macleay, the Plagiostomata of the Pacific, part 3 (plates 45, 46).—A. Sidney Olliff: Trogositidæ of Australia.—On a new species of Chrysophanus.—On Australian Ptinidæ.—W. A. Haswell, on some Australian Polychæta, part 1 (plates 50-55).—E. Meyrick, Australian Micro-Lepidoptera.—J. Brazier, a new Ochidium.—New land and fresh-water Mollusca from New Guinea.

Second series, vol. i. part 1, with 6 plates (May 25, 1886).—E. P. Ramsay and J. Douglas-Ogilby, descriptions of new Australian fishes; new species of fish from New Guinea; a new Coris from the New Hebrides.—E. P. Ramsay, on a new genus and species of fresh-water tortoise from the Fly River, New Guinea (plates 3-6).—George Masters, catalogue of Australian Coleoptera, part 3.—F. Ratte, *Crioceras australe*, Moore (?), a Lower Cretaceous fossil from Queensland (plates 1, 2).—Wm. Macleay, the insects of the Fly River, New Guinea.—C. W. de Vis, on some Geckos in the Queensland Museum.—A. S. Olliff, on a new Aphanipterous insect from New South Wales.—Wm. A. Haswell, on the myology of *Petaurista taguanoides*.—Capt. F. W. Hutton, the Mollusca of the Pareora and Oamaru systems of New Zealand.

Proceedings of the Royal Society of Queensland, vol. ii. parts 1 and 2, June 1886, contain, among others:—W. E. Armit, notes on the philology of the islands adjacent to the south-eastern extremity of New Guinea (pp. 2-12), and on the Papuans (pp. 78-116).—C. W. De Vis, on the bones and teeth of a large extinct lizard (pp. 25-31, plates 1-3).—On an extinct Ornithorhynchus (pp. 35-40, plate 4).—On some new species of Salarias, and on a new species and genus of lizard (pp. 56-61).—On a fossil Saurian (pp. 181-192, plates 10-15).—Henry Tryon, on Queensland harvesting-ants.—W. A. Tully, short account of the measurement of the base-line in connection with the trigonometrical survey of Queensland.—Baron von Müller, on a new tiliaceous tree (*Elæocarpus Bancroftii*) from North Eastern Australia.

Proceedings of the Royal Society of Tasmania for 1885 (Tasmania, 1886).—From the records of the *Proceedings* it is interesting to learn that, though the Society has lost the exclusive control over the Museum and Gardens, which now are managed by trustees, some of whom are elected by the Society, yet the work of the Society continues to develop, and its library to increase. This volume is accompanied by a sketch-map, coloured, giving the general geological features of Tasmania, by C. P. Sprent and R. M. Johnston; and a geological chart, by Mr. Johnston, showing the proposed provisional classification of the stratified rocks of Tasmania and their equivalents elsewhere.—Among the more important papers we note the following:—R. M. Johnston, various memoirs on the geology and palæontology of Tasmania.—R. A. Bastow, on the mosses and Jungermania of Tasmania.—W. F. Pettard, new Tasmanian marine shells.—Baron F. von Muller, notes on J. J. H. de Labillardière (with a portrait).—Capt. Shortt, earthquake-phenomena in Tasmania.—T. Stevens, on boring for coal in Tasmania.

ON THE OCCURRENCE OF CELLULOSE IN TUBERCULOSIS

CELLULOSE, the principal constituent of the vegetable cell-wall, has been found to occur also in some animals; the mantle of *Phallusia mamillaris* and of Cynthia, and the external coat of Salpa consist mainly of tunicin, or animal cellulose. Now a further very valuable contribution to our knowledge of the occurrence of this body has been made in Vienna by Herr Ernst Freund, working at Prof. E. Ludwig's laboratory. Freund has succeeded in preparing from some of the organs and blood of tuberculous persons a substance exactly resembling cellulose, and showing all the reactions which have hitherto been described as peculiar to the latter. The reactions employed were the following:—(1) Conversion of cellulose when dissolved in concentrated sulphuric acid into dextrose on boiling with dilute sulphuric acid; (2) resistance if treated with Schultze's reagent, a mixture of nitric acid and chlorate of potassium; (3) yielding of a collodion-like mass by the action of nitric acid and ether; (4) assuming a blue colour by the action of iodine in presence of concentrated sulphuric acid or chloride of zinc solution; (5) assuming a violet colour by the action of a naphthol when dissolved in concentrated sulphuric acid (Molisch's reaction); (6) insolubility in common (indifferent) solvents (dilute alkalies); (7) solubility in a solution of cupric hydroxide in ammonia. The substance obtained from miliary tubercles and from the blood of tuberculous persons was subjected to ultimate analysis in three cases, and yielded between 45·12 and 44·70 per cent. C, and between 6·41 and 6·19 per cent. H; while 44·74 per cent. C and 6·17 per cent. H corresponds to $C_6H_{10}O_5$. A quantitative determination of the cellulose of the tubercles has not been made. The researches were carried out on material from twenty-five tuberculous and thirty non-tuberculous cases. The tuberculous material (lungs, spleen, peritoneum with miliary tubercles, blood) embraced cases of conglomerated as well as of infiltrated tuberculosis in the different stages of the disease. The non-tuberculous material examined was taken partly from healthy organs, partly from organs affected by various diseases—as, *e.g.*, from pneumonia, emphysema, pulmonary gangrene—and failed to show any of the reactions described above. Carcinomatous, sarcomatous, lupoid, syphilitic, and other non-tuberculous granulations were also examined with negative results. From his researches Herr Freund makes the suggestion that in tuberculous growths and in the blood of tuberculous persons cellulose forms an intrinsic constituent. We need not refer to the importance and suggestiveness of Freund's discovery for pathological science, making further researches on this subject very desirable.

DISINFECTION BY HEAT

THE Annual Report for 1884 of the Medical Officer of the Local Government Board contained a memoir, by Dr. H. F. Parsons, on the subject of disinfection by heat. Of this memoir the leading points are here given.

In considering the applicability of heat as a means of disinfection, several distinct questions present themselves for solution. It has first of all to be determined what degree of heat and duration of exposure are necessary under different conditions, as of moisture and dryness, in order to destroy with certainty the activity of the contagia of infectious diseases.

We have next to ascertain how the required degree of heat may be made to penetrate through bulky and badly conducting articles, *e.g.* of clothing and bedding, for the disinfection of which the application of heat is especially employed.

We have also to learn whether such articles can be submitted to the required degree of heat without injury, for if not, disinfection presents little advantage over destruction.

After giving a *résumé* of the results of previous experiments to ascertain the degree of heat necessary to destroy the contagia of infectious diseases, from those of Dr. Henry published in the *Philosophical Magazine* for 1831, to those of Koch and his coadjutors (*Mittheilungen aus dem kaiserlichen Gesundheitsamte*, Berlin, 1881), the author states the results of a series of experiments made by him in conjunction with Dr. Klein, who prepared the infective materials, and, after these had been exposed to disinfecting processes, tested the results by inoculation on animals; control inoculations with unheated portions of the same materials being also in all cases made.

The following were the infective materials employed:—

(1) Blood of guinea-pig dead of anthrax, containing bacillus anthracis without spores.

(2) Pure cultivation of bacillus anthracis in rabbit broth, without spores.

(3) Cultivation of bacillus anthracis in gelatine, with spores.

(4) Cultivation of bacillus of swine fever (infectious pneumo-enteritis of the pig) in pork broth.

(5) Tuberculous pus, from an abscess in a guinea-pig which had been inoculated with tubercle.

Infectious pneumo-enteritis of the pig (swine fever) has been shown by Dr. Klein to be caused by the introduction into the body of the affected animal of a specific bacillus. This disease among pigs is highly infectious, the contagium being transmissible from pig to pig through the air, and persisting in infected buildings in a similar manner to the observed behaviour of small-pox and scarlet fever among human beings; and, though not transmissible to mankind, it can be inoculated upon rodents, although in the latter animals it is not contracted by infection received through the air.

The experiments on the disinfecting power of dry heat were mostly made in a copper hot-air bath, or in one improvised of flower-pots, and furnished with a Bunsen's regulator; those with steam were made in a felt-covered tin cylinder, through which passed a stream of steam from a kettle beneath.

The mode of procedure in exposing the materials to heat was as follows:—Strips of clean flannel were steeped in the respective infective fluids, dried in the air, wrapped separately and loosely in a single layer of thin blotting-paper, and suspended in the centre of the apparatus in company with a thermometer, so placed that its bulb was close to the packets of infected material.

The following were the results of the experiments with dry heat:—

Anthrax bacilli without spores were sterilised by exposure for five minutes only to a dry heat varying between 212° and 218° F.

Spore-bearing cultivations of the bacillus anthracis, on the other hand, did not lose their vitality by a two hours' exposure to 220° F., but were sterilised by exposure for four hours to 220° F., or one hour to 245° F.

A rabbit inoculated with swine fever virus which had been exposed to dry heat varying between 212° and 218° F. for an hour remained well; but one inoculated with virus exposed to a similar heat for only five minutes, died of swine fever after nineteen days, the usual time of death after inoculation being between five and eight days.

Guinea-pigs inoculated with tuberculous pus exposed for five minutes to 220° F. remained well.

The foregoing results, as far as regards anthrax, are far more favourable to the efficacy of dry heat as a disinfecting agent than those of Koch. It appears that the spores of the bacillus anthracis lost their vitality, or at any rate their pathogenic quality, after exposure for four hours to a temperature a little over the boiling-point of water, or for one hour to a temperature of 245° F. Non-spore-bearing bacilli of anthrax and of swine fever were rendered inert by exposure for an hour to a temperature of 212°–218°, and even five minutes' exposure to this temperature sufficed to destroy the vitality of the former, and impair that of the latter.

As none of the infectious diseases for the extirpation of which measures of disinfection are in practice commonly required are known to depend upon the presence of bacilli in a spore-bearing condition, it is concluded that, as far as our present knowledge goes, their contagia are not likely to retain their activity after being heated for an hour to 220° F.

In the experiments with steam the results were conclusive as to the destructive power of steam at 212° F. upon all the contagia submitted to its action. In one instance only was there room for suspicion that the disinfection had not been complete: this was in the case of the highly-resisting anthrax spores, exposed to steam for five minutes only: the animal had six days afterwards a swelling at the seat of inoculation, but remained well. On the other hand the animals inoculated with unheated portions of the same materials all died.

These results are in accordance with those of Koch, Gaffky, and Löffler, and it may be considered established that the complete penetration of an object by steam heat for more than five minutes is sufficient for its thorough disinfection.

In view of the above satisfactory results it was not deemed necessary to make any experiments as to the disinfecting power of steam at higher temperatures or under pressure, its efficacy being taken for granted.

Dr. Klein found that boiling in water for only one minute was sufficient to render inert the spores of the bacillus anthracis, although it is known that some of the spore-bearing non-pathogenic bacilli are only destroyed by prolonged boiling, or by a moist temperature above the boiling-point.

Some observations were made on the destruction of lice by heat. It was found that the eggs of lice could be conveniently hatched by tying up tightly in muslin a small piece of the garment on which they were deposited, and carrying it about for a week or two in a warm pocket. Tested in this way no development was found to take place in eggs of lice which had been exposed for one hour to 300° F. dry heat, for one hour to 230 F. dry heat, or for ten minutes to steam at 212° F., or which had been boiled for five minutes in water. The maximum heat which lice or their eggs will bear with impunity was not ascertained.

In order to secure the thorough and certain disinfection by heat of porous articles likely to retain infection, such as clothing and bedding, it is necessary that the heat should be made to permeate the articles in every part to such a degree and for such a length of time as to destroy all infectious matter which they may contain.

It has been remarked that such articles as bedding and blankets are the highest outcomes of the ingenuity of man to check the passage of heat from one side of the object to the other. It is no wonder, therefore, that they should be found difficult of penetration by heat. Even thin layers, however, of badly conducting substances interpose a considerable barrier to the passage of dry heat. The following experiment was made to ascertain how far the inclosing of infective objects in blotting-paper or test-tubes plugged with cotton wool (as in Dr. Koch's experiments) hindered the full access of heat to them.

Two similar registering thermometers were taken: the bulb of one was tied up in a single layer of thin white blotting-paper, that of the other was placed in a test-tube ⅞ inch wide in such a manner as not to touch the sides, and a plug of white cotton wool 1 inch deep was pushed into the tube around the stem of the thermometer, but not as far as the bulb. Both the paper and cotton wool were previously dried. The two thermometers, together with another with bare bulb, were then hung up in a hot-air bath. Heat being applied, the thermometers were read half-hourly as follows:—

Time from lighting	Readings of thermometer with bulb: Bare ° F.	In paper ° F.	In tube ° F.
½ hour ...	162	147	151
1 hour ...	212	193	196
1½ hour ...	234	213	219
2 hours ...	242	236	238
2½ hours ...	244	244	244

The following experiment was made with a thermometer having the bulb covered with a single layer of blanket and placed in the hot-air bath already heated:—

Time from placing in hot-air bath	Thermometer with bulb bare ° F.	Thermometer with bulb in blanket ° F.
½ hour ...	246	231
1 hour ...	260	250
1½ hour ...	266	254
2 hours ...	268	263
2½ hours ...	268	264

Experiments made with larger articles and apparatus showed how difficult it was to secure the penetration of a dry heat sufficient for disinfection into the interior of such an object as a pillow. It was only effected by employing a high degree of heat, or by continuing the exposure during many hours, length of exposure compensating for a lower degree of heat. On the other hand heat in the form of steam penetrates much more rapidly than dry heat. Thus a thermometer in a roll of dry flannel placed in a hot-air bath at 212° F., at the end of an hour registered only 130° F. In the same roll, placed in the steam cylinder for ten minutes, the thermometer marked 212° F. Experiments on the large scale were equally conclusive. The causes of the superior penetrative power of heat in the form of steam over hot air appear to be:—

(1) The large amount of latent heat in steam, set free on its condensation. In hot dry air, on the other hand, the evaporation of hygroscopic moisture takes up heat and delays the attainment of the required temperature.

(2) Steam, on condensation into water, occupies but a very small fraction of its former volume and thus makes room for more. Hot air in cooling diminishes in volume in much less proportion.

(3) The heat evolved in the moistening of a dry porous substance. In the centre of a highly-dried roll of flannel placed in the cylinder in a current of steam at 212° F., a thermometer, after five minutes' exposure, registered 239° F.

(4) The higher specific heat of steam than of air.
(5) The greater diffusive power of steam than of air.
(6) The effects of pressure. By applying steam under pressure, relaxed and reapplied from time to time, so as to displace the cold air remaining in the interstices of the material, we have a means of considerably increasing the penetrative power of the steam.

In view of the superior efficacy of steam, both in the destruction of infective matters and in the penetration of badly-conducting materials, some experiments were made with moist air in the hope that it might be found possible to obtain the advantages of the use of steam without its drawbacks.

In these experiments either an evaporating vessel containing water was placed at the bottom of the hot-air chamber, or steam evolved in a separate boiler was led into the chamber by a pipe.

An attempt was made to measure the degree of humidity of the air by suspending in the chamber two maximum-registering thermometers arranged side by side, one of them having its bulb covered with gauze kept moist by dipping in a phial of water, as in the wet-and-dry-bulb arrangement employed by meteorologists. It appears, however, that there are no tables or formulæ in existence by which the degree of humidity of the air corresponding to a given difference between the wet and dry bulb thermometers at these high temperatures can be ascertained. The conditions in a heated chamber are so different from those met with in meteorological practice, that it is doubtful whether the relative humidity of the air could be obtained in this way with any great degree of accuracy; but a comparison of the readings of the wet and dry bulb thermometers was found in practice to be useful as a rough indication of the dryness or dampness of the air, although the readings could not be reduced to a common measure.

The experiments seem to show conclusively that moistening the air of the heated chamber diminishes the time necessary for the penetration of heat into a badly-conducting object. As examples the following observations may be quoted. They were made in an iron chamber heated by a furnace underneath, and furnished with a pipe by which steam could be admitted.

		No steam admitted	A small jet of steam admitted	Large jet of steam admitted
Maximum readings of thermometers hung up in chamber	Dry bulb	299° F.	299° F.	249° F.
	Wet bulb	146°	165°	190°
Temperature attained in centre of similar pillows exposed for one hour in heated chamber		136°	188°	209°

The moistening of the air of the heated chamber by either method was further found to have the advantage of rendering more equable the distribution of temperature in different parts of the chamber, thus tending to prevent scorching of the articles placed therein.

On the other hand it was not found that the presence of moisture in proportions such as these, or even greater, increased the disinfecting effect at the temperature employed; spores of the bacillus anthracis retained their vitality equally well in heated air whether it were moist or dry; thus they caused the death of a guinea-pig after exposure for an hour to a temperature of {dry bulb 220° F., wet bulb 190° F.} whereas five minutes' exposure to a current of steam at 212° F. was sufficient to render them inert.

To avoid risk of injury to articles subjected to disinfection by heat is an important practical question, not only on account of the value of the articles themselves, but also because, if the exposing of such articles to heat be attended with risk of injury, there is danger lest, to avoid this risk, they may not be sufficiently heated to insure disinfection. The following are the principal modes in which injury may occur; they are somewhat different in the case of steam from that of dry heat:—

1. Scorching or partial decomposition of organic substances by heat. In its incipient stages this manifests itself by changes of colour, changes of texture, and weakening of strength.
2. Overdrying, rendering materials brittle (by dry heat).
3. Fixing of stains, so that they will not wash out.
4. Melting of fusible substances, as wax and varnish, and ignition of matches accidentally left in pockets.
5. Alterations in colour, gloss, &c., of dyed and finished goods.
6. Shrinkage and felting together of woollen materials.
7. Wetting (by steam).

Scorching begins to occur at different temperatures with different materials, white wool being soonest affected. It is especially apt to occur where the heat is in the radiant form. To avoid risk of scorching the heat should not be allowed much to exceed 250° F., and even this temperature is too high for white woollen articles.

By a heat of 212° and upwards, whether dry or moist, many kinds of stains are fixed in fabrics so that they will not wash out. This is a serious obstacle in the way of the employment of heat for the disinfection previous to washing of linen, &c., soiled by the discharges of the sick.

Steam disinfection is inapplicable in the case of leather, or of articles that will not bear wetting. It causes a certain amount of shrinkage in textile materials, about as much as an ordinary washing. The wetting effect of the steam may be diminished by surrounding the chamber with a jacket containing steam at a higher pressure, so as to superheat the steam in the chamber.

For articles that will stand it, washing in boiling water (with due precautions against re-infection) may be relied on as an efficient means of disinfection It is necessary, however, that before boiling the grosser dirt should be removed by a preliminary soaking in cold water. This should be done before the linen leaves the infected place.

The objects for which disinfection by dry heat or steam is especially applicable are such as will not bear boiling in water, *e.g.*, bedding, blankets, carpets, and cloth clothes generally.

Apparatus for disinfection by heat may be classified as follows:—

(a) *By hot air*—
1. Apparatus in which the heat is applied to the outside o the chamber, and the products of combustion do not enter the interior.
2. Apparatus in which the heated products of combustion enter the interior.
3. Apparatus heated by steam or hot water circulating in closed pipes.
4. Apparatus in which air previously heated is blown into the chamber.

(b) *By steam*—
5. By a current of free steam.
6. By steam confined in a chamber at pressures above that of the atmosphere.

The most important requisites of a good apparatus for disinfection by heat are (*a*) that the temperature in the interior shall be uniformly distributed; (*b*) that it shall be capable of being maintained constant for the time during which the operation extends; and (*c*) that there shall be some trustworthy indication of the actual temperature of the interior at any given moment. Unless these conditions be fulfilled, there is risk, on the one hand, that articles exposed to heat may be scorched, or on the other hand, that through anxiety to avoid such an accident the opposite error may be incurred, and that the articles may not be sufficiently heated to insure their disinfection.

In dry-heat chambers the requirement (*a*) is often very far from being fulfilled, the temperature in different parts of the chamber varying sometimes by as much as 100°. This is especially the case in apparatus heated by the direct application of heat to the floor or sides of the chamber. The distribution of temperature is more uniform in proportion as the source of heat is removed from the chamber, so that the latter is heated by currents of hot air rather than by radiation.

There is a marked difference between the distribution of temperature in a chamber heated primarily by radiant heat and in one heated by the admission of hot air or steam. Radiant heat is most intense close to its source, diminishing rapidly as we recede therefrom. Also it does not turn corners, and thus objects lying behind others are screened from it, except so far as it may be reflected upon them from other surfaces. The rays strike the walls of the chamber and objects therein, so that these are more highly heated than the air, which becomes heated only secondarily by contact with them.

On the other hand, if air already heated, or steam, be admitted into a chamber, the temperature tends to equalise itself in the different parts, and the walls and solid contents of the chamber do not become hotter than the air.

In chambers heated by gas, when once the required temperature has been attained, but little attention is necessary to maintain it uniform, and in the best-made apparatus this is automatically

performed by a thermo-regulator. On the other hand, in apparatus heated by coal or coke the temperature continually tends to vary, and can only be maintained uniform by constant attention on the part of the stoker.

In very few hot-air chambers did the thermometer with which the apparatus was provided afford a trustworthy indication of the temperature of the interior; in some instances there was an error of as much as 100° F. This is due to the thermometer, for reasons of safety and accessibility, being placed in the coolest part of the chamber, and to the bulb being inclosed for protection in a metal tube which screens it from the full access of heat. The difficulty may be overcome by using, instead of a thermometer, a pyrometer actuated by a metal rod extending across the interior of the chamber.

In steam apparatus the three requirements above mentioned are all satisfactorily met, and for this reason, as well as on account of the greater rapidity and certainty of action of steam, both in penetrating badly conductive materials and in destroying contagia, steam chambers are, in Dr. Parsons's opinion, greatly preferable to those in which dry heat is employed.

It is important that the arrangements of the apparatus, the method of working, and the mode of conveyance to and fro, should be such as to obviate risk of articles which have been submitted to disinfection coming into contact with others which are infected.

The latter part of the Report is taken up with descriptions of the various forms of apparatus in use for disinfection by heat, and accounts of experiments made with a view to test their practical efficiency.

ON THE FRACTIONATION OF YTTRIA[1]

HAVING already explained the methods of chemical fractionation, it may be useful now to describe some of the results yielded by an extended perseverance in these operations.

I must, in the first place, explain that my work has been confined to a limited and very rare group of bodies—the earthy bases contained in such minerals as samarskite, gadolinite, &c. These have been repeatedly put through the fractionation mill by other chemists, but the results have been most unsatisfactory and contradictory, no sufficiently good test being known whereby the singleness of any earth got out by fractionation could be decided, except the somewhat untrustworthy one of the atomic weight. I say *untrustworthy*, because it is now known that fractionation, unless it is pushed far beyond the point to which some Continental chemists have even carried it, is quite as liable to give *mixtures* which refuse to split up under further treatment of the same kind, as it is to yield a chemically simple body. This I have fully gone into in my paper "On the Methods of Chemical Fractionation." The unsatisfactory nature of fractionation work may be seen from expressions used, in private letters to me, by some of the eminent chemists who have almost made this method their own. One writes—"It is very tiresome working with the rare earths, as we never can be sure when we have got a definite result. There will never be an end to their history. I am very tired of it, and am much inclined to give it up." Another writes—"Unfortunately I commenced my researches on the rare earths with too little material, and I have not had the courage, at my age, to recommence the work on more abundant material. The further I advance in my work the more I am convinced that no known method permits of the complete separation of these different earths one from the other." A third writes—"One loses so much material in the separations that it appears to me scarcely possible, with the material available, to arrive at a successful solution of the question." I could multiply similar quotations, all breathing the same almost despairing spirit.

It would certainly not have been prudent on my part to invite a time-honoured comparison, and "rush in" where so many eminent men "fear to tread," were it not that good fortune had placed in my hands a physical test for these obscure molecular groupings which is of the most exquisite sensitiveness. I refer to what I have for shortness called the Radiant-Matter test.

It is well known that a limited group of these rare earths, when phosphoresced *in vacuo*, yield discontinuous spectra. The method adopted to bring out the spectra is to treat the substance under examination with strong sulphuric acid, drive off excess of acid by heat, and finally to raise the temperature to dull redness.

[1] A Paper read before Section B of the British Association at the Birmingham meeting, by William Crookes, F.R.S., V.P.C.S

It is then put into a radiant-matter tube of the form shown in Fig. 1, and the induction spark is passed through it after the exhaustion has been pushed to the required degree. The phosphorescence occurs beneath the negative pole. As each gaseous molecule, carrying its charge of negative electricity with it, strikes the earthy sulphate, it has a tendency to part with its charge, provided it finds a body ready to take up the electricity; otherwise it retains its charge. Bodies like yttrium sulphate, &c., easily take the electric charge, and under the stimulus phosphoresce, emitting light whose waves tend to collect round definite centres of length. The phosphorescent light which the discharge evokes is best seen in a spectroscope of low dispersion, and with not too narrow a slit. In appearance the bands are more analogous to the absorption-bands seen in solutions of didymium than to the lines given by spark spectra. Examined with a high magnifying power, all appearance of sharpness generally disappears: the scale measurements must therefore be looked upon as approximate only; the centre of each band may be taken as accurately determined within the unavoidable errors of experiment, but it is impossible to define their edges with much precision. The bands are seen much sharper when the current first passes than after the current has been passing for some time and the earth has become hot. On cooling, the sharpness of the bands re-appears.

As a general rule, the purer the earth the sharper the band, and when impurities are removed to the utmost extent, the sharpness is such as to deserve the name of a line. This may be illustrated by mixing together yttria and lime. Lime phosphoresces with a continuous and yttria with a discontinuous spectrum. Mixed together, the phosphorescing energy of the lime does not spend itself over the whole spectrum, but concen-

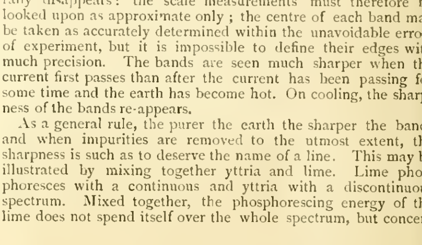

FIG. 1.

trates itself in greatly reinforcing the yttria bands. A molecule of yttria vibrating with a definite wave-length gives a nearly sharp line, but the molecule of lime with which it is weighted has no special tendency to vibrate to one wave-length more than another. The yttria induces the right vibration in the adjacent molecule of lime; but this lime, once set in vibration, cannot confine itself to the exact wave-length required, and overflows a little on each side, and the result is a widening and blurring of the bands, becoming greater in amount as the extraneous earth increases in quantity.

To this rule one exception occurs. The body which I have named Sδ, or 609, is remarkable for the great sharpness of its phosphorescent line, and I have noticed scarcely any variation in its sharpness, however large the bulk of extraneous earth associated with it. This line, however, is sharper and brighter when the current is first turned on than it is after the earth has been phosphorescing for a minute or so.

In the Bakerian lecture on yttrium delivered before the Royal Society (*Phil. Trans.* Part 3, 1883), I described the phosphorescent spectrum given by this element, and in the address which I have had the honour of delivering before this Section I gave a drawing of the spectrum of yttrium, together with a sketch of the train of reasoning by which I had been led to the opinion that excessive and systematic fractionation had split up this stable molecular group into its components, distributing its atoms into several groups, with different phosphorescent spectra.

No longer than twelve months ago the name yttria conveyed a perfectly definite meaning to all chemists. It meant the oxide of the elementary body yttrium. I have in my possession specimens of yttria from M. de Marignac (considered by him to be purer than any chemist had hitherto obtained), from M. Clève (called by him "purissimum"), from M. de Boisbaudran (a sample of which is described by this eminent chemist as "scarcely

soiled by traces of other earths"), and also many specimens prepared by myself at different times and purified up to the highest degree known at the time of preparation. Practically these earths are all the same thing, and up to a year ago every living chemist would have described them as identical, *i.e.* as the oxide of the element yttrium. They are almost indistinguishable one from the other both physically and chemically, and they give the phosphorescent spectra *in vacuo* with extraordinary brilliancy. This is what I formerly called yttria, and have more recently called *old* yttria Now these constituents of old yttrium are not *impurities* in yttrium any more than praseodymium and neodymium (assuming them really to be elementary) would be impurities in didymium. They constitute a veritable splitting up of the yttrium molecule into its constituents.

The plan adopted in the fractionation of yttria does not differ in principle from the methods described in my former paper "On the Methods of Chemical Fractionation." Dilute ammonia is added to a very dilute solution of the earth in only sufficient quantity to precipitate one half. After standing for several hours the precipitate is filtered. After each fractioning the filtrate is passed to the left and the precipitate to the right, and the operations are continued many thousand times.

The diagram (Fig. 2) shows the scheme clearly, with the direction the precipitates and solutions travel. Limited space, even on a large diagram, prevents me from giving more than a few operations, but they will be sufficient to satisfy you that enormous patience, a large amount of material, and a not insignificant number of bottles, are requisites for successful fractionation. Such proceedings are tedious enough even in their narration, but no mere words can enable any one to realise the wearisome character of these operations when repeated day by day, month after month, on long rows of Winchester quart bottles.

After a certain time, on examining the series of earths in the lowest line of bottles, their phosphorescent spectra are found to alter in the relative intensities of some of the lines, and ultimately different portions of the fractionated earths show spectra such as I have endeavoured to illustrate at the foot of the diagram (Fig. 2), where I give the spectra of five components of yttrium.

The final result to which I have come is that there are certainly five, and probably eight, constituents into which yttrium may be split. Taking the constituents in order of approximate basicity (the chemical analogue of refrangibility), the lowest earthy constituent gives a deep blue band, Gα (λ 482); then there is a strong citron band, Gδ (λ 574), which has increased in sharpness

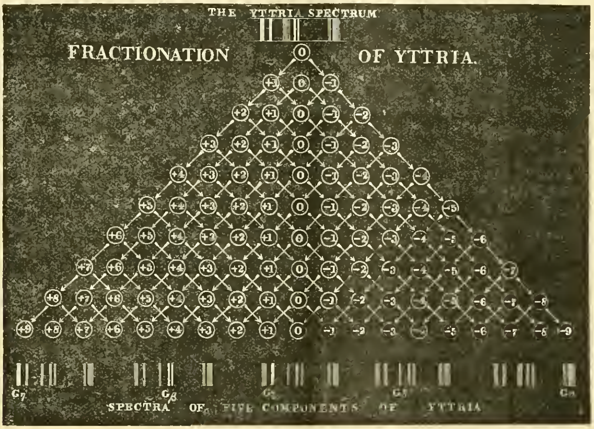

FIG. 2.

till it deserves to be called a line; then come a close pair of greenish-blue lines, Gβ (λ 549 and λ 541, mean 545); then a red band, Gζ (λ 619), then a deep red band, Gη (λ 647), next a yellow band, Gε (λ 597), then another green band, Gγ (λ 564); this (in samarskite and cerite yttria) is followed by the orange line Sδ (λ 609). The samarium bands remain at the highest part of the series. These, I am satisfied, are also separable, although for the present I have scarcely touched them, having my hands fully occupied with the more easily resolvable earths. The yellow band, Gε, and green band, Gγ, may in fact be due to a splitting up of samarium.

Until we know more about these bodies I refrain from naming them, but will designate them provisionally by the mean wavelength of the dominant band. If, however, for the sake of easier discussion among chemists a definite name is thought to be more convenient, I will follow the plan frequently adopted in such cases, and provisionally name these bodies as shown in the table given below.

The initial letters S and G recall the origin of the earths respectively from Samarskite and Gadolinite.

Not only has yttrium been split up by subjection to fractionation, but samarium, as I have hinted above, is likely to prove equally unable to resist this operation. In the phosphorescent spectrum of samarium sulphate the line Sδ (609) is one of the constituents. When yttria is added to samaria this line is developed in greater intensity, as yttria has the power of deadening the other bands of samarium, while it does not seem to affect the

Position of lines in the spectrum	Scale of spectroscope	Mean wave-length of line or band	$\frac{1}{\lambda^2}$	Provisional name	Probability
Bright lines in—					
Deep blue ...	8·931	482	4304	Gα	New
Greenish-blue (mean of a close pair...)	9·650	545	3367	Gβ	New, or the Zβ of M. de Boisbaudran
Green........ ..	9·812	564	3144	Gγ	New
Citron	9·890	574	3035	Gδ	New, or the Zα of M. de Boisbaudran
Yellow.........	10·050	597	2806	Gε	New
Orange..	10·129	609	2693	Sδ	New
Red	10·185	619	2611	Gζ	New
Deep red......	10·338	647	2389	Gη	New

line Sδ. Several circumstances, however, tend to show that although line Sδ accompanies samarium with the utmost per-

tinacity, it is not so integral a part of its spectrum as the other red, green, and orange lines. For instance, the chemical as well as physical behaviour of these line-forming bodies is different. On closely comparing the spectra of specimens of samaria from different sources, line Sδ varies much in intensity, in some cases being strong and in others almost absent; the addition of yttria is found greatly to deaden the red, orange, and green lines of samarium, while yttria has little or no effect on the line Sδ; again, a little lime entirely suppresses line Sδ, while it brings out the samarium lines with increased vigour. Finally, attempts to separate line Sδ from samarium and those portions of the samarskite earths in which it chiefly concentrates has resulted in sufficient success to show me that, given time enough, and an almost inexhaustible supply of material, a separation would not be difficult. These facts, together with the peculiar behaviour of the lines Gε and Gγ, strengthen my suspicion as to the resolvability of samarium.

Samaria giving the line Sδ had been prepared from cerite and samarskite. Many observations had led me to think that the proportion of band-forming constituents varied slightly in the same earth from different minerals. Amongst others, gadolinite showed indications of such a differentiation, and therefore I continued the work on this mineral. Very few fractionations were necessary to show that the body giving line Sδ was not present in the gadolinite earths; no admixture of yttria and samaria from this source giving a trace of it. It follows, therefore, that the body whose phosphorescent spectrum gives line Sδ occurs in samarskite and cerite, but not in gadolinite.

It now became an interesting inquiry whether all these constituents of yttrium were united together in exactly the same proportion in every case. A glance at the diagram will show that yttrias from different sources, although they may be alike as far as our coarser chemical tests are concerned, are not built up exactly in the same manner. Thus, when the samarskite yttrium was forming, all the constituent molecules—which I have provisionally named Gα, Gβ, Gγ, Gδ, Gε, Gζ, Gη, and Sδ—condensed together in fair proportion. In gadolinite yttrium the constituents Gβ and Gδ are plentiful, Gζ is very deficient, Sδ is absent, and the others occur in moderate quantities. In the yttrium from xenotime Gδ is most plentiful, Gβ occurs in smaller proportion, Gζ is all but absent, and Sδ is quite absent. Yttrium from monazite contains Gβ and Gδ, with a fair proportion of the other constituents, Gβ is plentiful and the red is good. Yttrium from fluocerite is very similar to that from monazite, but Gα is weaker. Yttrium from hielmite is very rich in Gδ, has a fair quantity of Gα and Gβ, less of Gγ, no Sδ, and only a very faint trace of Gη. Yttrium from euxenite is almost identical with that from hielmite. Yttrium from cerite contains most Gζ and Gδ, less Gα and Gβ, only a trace of Gη, and a fair proportion of Sδ.

I have already mentioned how the key to these explanations was gained by an examination of the phosphorescent spectrum of M. de Marignac's Yα (now called by him gadolinium).

Referring to the diagram, it is seen that Yα is composed of the following band-forming bodies:—Gβ, Sδ, Gζ, together with a little samarium. Calling the samarium an impurity, it is thus seen that gadolinium is composed of at least three simpler bodies.

It is by a method of his own, differing from mine, that M. de Boisbaudran has obtained phosphorescent spectra of some of the rare earths. He takes the induction-spark between the surface of a strong and acid solution of the metallic chloride and a clean platinum wire a few millims. above it. The platinum wire is kept negative and the solution positive; it is then observed that in many cases a thin layer of fluorescent light is seen at the surface of the liquid. This layer gives a spectrum of nebulous bands. For the sake of brevity I will adopt M. de Boisbaudran's term, and call this process the *method of reversion* (the direction of the spark being reversed). As this method is entirely different to the one I adopt, it is not surprising that the results are also different. Experimenting in this way M. de Boisbaudran has obtained, among others, two bands (λ 573 and λ 543·2), which he considers are caused by two elements, named respectively Zα and Zβ, and which he considers new, at all events if we except terbium and possibly the elements of what was formerly called holmium. His method fails to show any spectrum in solutions of yttria which by my method give the yttria bands with the greatest brilliancy; while conversely his method shows a fluorescent spectrum in solutions of earths separated as widely as possible from yttria, chemically as well as spectroscopically. My experiments on both these methods tend to the conclusion that our bands are not due to the same cause, although M. de Boisbaudran's experiments have led him to the opposite conclusion. The band of Zβ (543) falls between the double green band Gβ, and the band of Zα (573) would come very near the citron line Gδ.

In the hands of a practised experimentalist like M. de Boisbaudran this method may give trustworthy indications, but I must confess that in my opinion the test is one beyond the range of practical analysis, owing to the enormous difficulty of getting the phenomena described by the discoverer. Unless the strength of spark, the concentration and acidity of solution, and the dispersion and magnifying power of the spectroscope bear a certain ratio one to the other, the observer is likely to fail in seeing a spectrum even in solutions of earths which contain considerable quantities of Zα and Zβ. In my own case I not only have had the advantage of personal instruction in Paris from M. de Boisbaudran himself in the best method of getting these reversion spectra, but on returning to London I brought with me some of the identical earths which give these spectra at their best. In spite of these advantages I have sometimes experimented off and on for weeks without being able to see more than a feeble glimmer of the bands described by M. de Boisbaudran.

Again, when everything is most favourable and the reversion bands are at their strongest, they are but a faint and hazy shadow of the brilliant lines given by the bombardment process. M. de Boisbaudran, speaking of the relative sensitiveness of our two methods, says that the bombardment process *in vacuo* is incomparably more delicate than his reversion test, and I estimate the relative sensitiveness of the two methods to be in the proportion of about 1 to 100.

You have probably anticipated in your minds a question which is likely to occur at this point of the inquiry. If such results have been obtained by submitting yttrium to this novel method of analysis, what will be the result of fractionating some other reputed element?

Yttrium, as I have explained, is an exceedingly stable molecular group, capable of acting as an element, just as calcium, for instance, acts as an element: to split up yttrium requires not only enormous time and material, but the existence of a test by means of which the constituents of yttrium are capable of recognition. Had we tests as delicate for the constituent molecular groups of calcium, this also might be resolved into simpler groupings. It is one thing, however, to find out means of separating bodies which we know to be distinct and have colour or spectrum reactions to guide us at every step; it is quite another thing to separate colourless bodies which are almost identical both in chemical reaction and atomic weight, especially if we have no suspicion that the body we are dealing with is a mixture.

(I mention calcium because it is one of several other elements which I have put through the fractionation mill. Many hundred operations have given me just sufficient encouragement to make me wish I had time to push this work to the end.)

One of the chief difficulties in the successful carrying out of an investigation in radiant-matter spectroscopy is the extraordinary delicacy of the test. This extreme sensitiveness is a drawback rather than a help. To the inexperienced eye 1 part of yttrium in 10,000 gives as good an indication as 1 part in 10, and by far the greater part of the chemical work undertaken in my hunt for spectrum-forming elements was performed upon material which later knowledge shows did not contain sufficient to respond to any known chemical test. It is as if the element sodium were to occur in ponderable quantity only in a few rare minerals seldom seen out of the collector's cabinet. With only the yellow line to guide, and seeing the brilliancy with which an imponderable trace of sodium in a mineral declares its presence in the spectrum, I venture to think that a chemist would have about as stiff a hunt before he caught his yellow line as I have had to bring my orange and citron bands to earth.

Chemistry, except in few instances, as water-analysis and the detection of poisons, where necessity has stimulated minute research, takes little account of "traces," and when an analysis adds up to 99·999, the odd 0·001 per cent. is conveniently put down to "impurities," "loss," or "errors of analysis." When, however, the 99·999 per cent. constitutes the impurity, and this exiguous 0·001 is the precious material to be extracted, and when, moreover, its chemistry is absolutely unknown, the difficulties of the problem become enormously enhanced. Insolubility as ordinarily understood is a fiction, and separation by preci

pitants is nearly impossible. A new chemistry has to be slowly built up, taking for data uncertain and deceptive indications, marred by the interfering power of mass in withdrawing soluble salts from a solution, and the solubility of nearly all precipitates when present in traces in water or in ammoniacal salts. What is here meant by "traces" will be better under tood if I give an instance. After fifteen months' work I obtained the earth yttria in a state which most chemists would call absolutely pure, for it contained not more than 1 part of impurity (samaria) in 250,000 parts of yttria. But this one part in a quarter of a million profoundly altered the character of yttria from a radiant-matter-spectroscopic point of view, and the persistence of this very minute quantity of interfering impurity entailed another ten months' extra labour to eliminate these final "traces," and to ascertain the real reaction of yttria pure and simple.

The radiant-matter test applied to these phosphorescing bodies proves itself to be every day more and more valuable, and one of the most far-searching and trustworthy tools ever placed in the hands of the experimental chemist. It is an exquisitely delicate test, capable of being applied to bodies which have been approximately separated, but not yet completely isolated, by chemical means; its delicacy is unsurpassed even in the region of spectrum analysis; its economy is great, inasmuch as the test involves no destruction of material; and its convenience is such that any given specimen is always available for future reference. Likewise, the quantity of material is limited solely by the power of the human eye to see the body under examination. Beyond all these excellences is its trustworthiness. I should perhaps exceed the legitimate inference from experience were I to claim that this test is infallible; but this I may say—during the five years in which the test has been in daily use in my laboratory, I never once have been led to view its indications with suspicion. Anomalies and apparent contradictions have cropped up in plenty; but a little more experiment has always shown that the anomalies were but finger-posts pointing to fresh paths of discovery, and the contradictions were due to my own erroneous interpretation of the facts before me.

SCIENTIFIC SERIALS

Rendiconti del Reale Istituto Lombardo, July.—On some new substituted derivatives of benzine, by E. G. Körner. In order to complete the still defective aromatic series, the author has prepared a number of these derivatives, studying them in connection with the relative isomerous compounds. The list includes a hydrochlorate, $(B)HCl, H_2O$; a sulphate, $(B)2H_2SO_4$; orthoiodacetanilide. $C_6H_4I . NHC_2H_3O$; and nitro-orthobiiodobenzine, probably $C_6H_2 . I . I . H . NO_2$.—On the effects of the sulphate of copper against the parasites of the grape-vine, by Prof. Gaetano Cantani. It is shown that this remedy, which has already been successfully tried in France, should also be introduced in Italy, if not to supersede, at least jointly with, the milk of lime.—Chemical and experimental researches on human milk, by Prof. G. Sormani and T. Gigli. It appears from the authors' experiments that a mixed or normal diet yields far better results than an exclusively animal or vegetarian *régime*.—Meteorological observations made at the Brera Observatory, Milan, during the month of July.

Botanische Jahrbücher, von A. Engler, Siebenter Band, Heft iv.—Contributions to the morphology and classification of the Cyperaceæ, by Dr. F. Pax. The author regards the Cyperaceæ as reduced types of a series which is more advanced phylogenetically than the Juncaceæ. As regards their relations to the Gramineæ, he concludes that the affinity is not so direct that the one family could be derived from the other.—On the flower and inflorescence of the Centrolepidaceæ, by Prof. Dr. G. Hieronymus.—Contributions to the flora of the Cameroons, by A. Engler. A list of plants collected by Dr. Buchholz in the Cameroons in 1874, with descriptions of the new species.—On the origin of the weeds on arable land and waste places in Germany, part 1, by F. Hellwig.—Abstracts of important papers.

Heft v. opens with part 2 of the above paper by Dr. Hellwig. The first part is chiefly occupied with the general consideration of the subject, and lists of the plants in question; while the second contains a detailed account of the origin of the plants named in the foregoing lists.—The orchids collected by Dr. Naumann on the expedition of H.M.S. *Gazelle*, by F. Kränzlin. The volume closes with a valuable list of works published during 1885, on classificatory botany, &c. This, together with the frequent analyses of the more important of those papers which are published in languages not usually familiar to ordinary readers, greatly enhances the value of Dr. Engler's excellent serial.

Bericht über die Thätigkeit der botanischen Section der Schlesischen Gesellschaft, 1885, compiled by Prof. Dr. F. Cohn.—The Botanical Section of the Society held nine meetings during the year 1885, at which the following original papers were read:—Dr. Engler, on the vegetation of the German possessions in South Africa.—Dr. Pax, on the genus Acer.—Herr Limpricht, on the formation of pores in the cortex of the Sphagna.—Dr. Eidam, on an Entomophthoraceous fungus found on frogs' dung.—Dr. Schröter, on the mycological results of a journey to Norway.—Dr. Pax, on the morphology and classification of the Cyperaceæ.—Dr. Engler, on the family of the Typhaceæ.—The report closes with a statement of the results of the investigation of the Phanerogamic flora of the district in 1885, arranged by R. von Uechtritz.

Beiträge zur Biologie der Pflanzen, von Dr. F. Cohn, Vierter Band, Zweites Heft.—Investigations on the tendrils of the *Cucurbitaceæ*, by Dr. Otto Müller, of Breslau (3 plates). The author concludes, chiefly on anatomical grounds, that the irritable part of the tendril of the Cucurbitaceæ is of foliar nature.—Investigations of the *Flagellatæ*, by Dr. Arthur Seligo (1 plate).—*Basidiobolus*, a new genus of the *Entomophthoraceæ*, by Dr. Ed. Eidam (4 plates). The author regards the resting spores of this genus as true zygospores, though the gametes are of unequal size, and expresses the opinion that the *Entomophthoreæ* find their natural place in the *Zygomycetes*, as directly related to the *Mucorini*.

SOCIETIES AND ACADEMIES

SYDNEY

Royal Society of New South Wales, August 4.—Ch. Rolleston, President, in the chair.—The Society's Medal and Prize of 25*l*. was presented to Mr. S. Herbert Cox, F.C.S., F.G.S., for his prize essay on "The Tin Deposits of New South Wales." The principal deposits occur in New England as impregnations, segregation veins, and lodes in granite, also as gash veins in Silurian slates, and as a network of veins or stockwork in haplite. The granitic eruption occurred not later than Carboniferous times, and no sedimentary strata appear to have been deposited until the Tertiary period, when the leads of alluvial tin were formed, together with their associated gravels. Denudation on an enormous scale has gone on, and the Silurian slates which rest on the granites have only been preserved as outlying patches included in folds in the granite. Dykes of feldspar and quartz porphyry traverse both the granite and slates, but the date of this eruption is probably Tertiary, although evidence appears to point out that this acidic only preceded the ensuing basaltic eruption by a short time. The more fluid basalt flowed for considerable distances, frequently burying the gravels of the river-beds with the tin they contained, and preserving these "deep leads" from subsequent denudation. True lodes appear to be rare, but some remarkable impregnated areas exist in greisen; "segregation" veins of small size are found in the granite, and in the slate "gash" veins up to 4 inches in width occur, but these are certainly not true lodes. Fortunately, wolfram occurs in separate veins from the tin; copper and iron pyrites, fluor-spar, tourmaline, white mica, and topaz are common; beryl forms a rock with quartz, through which tinstone is impregnated. In the alluvial deposits, tinstone is found associated with diamonds, sapphires, zircons, &c. The greater quantity of the tinstone hitherto raised has been from the alluvial, and the "deep leads" which are still being worked, and will probably be greatly developed in the future, closely correspond in their course with the shallow ones. They are worked to depths of 140 to 180 feet, and are frequently found below solid floes of basalt. Very good crushing and smelting plants have been erected, and although the conditions of the district vary greatly in different parts, it may be taken as certain that a yield of 5 per cent. tin in lodes, and from $\frac{1}{2}$ to 1 cwt. per cubic yard in deep alluvial deposits, pays for extraction. The total output of tin between 1872 and 1883 is 64,794 tons of ingots and 13·268 tons of black tin.—A paper by the late Rev. P.

MacPherson, M.A , was also read, on the aboriginal names of rivers in Australia philologically examined.

PARIS

Academy of Sciences, October 27.—M. Jurien de la Gravière, President, in the chair.—On Dr. Spœrer's views regarding the solar spots and protuberances, by M. Faye. In a paper recently contributed to the *Proceedings* of the German Astronomical Society, M. Spœrer adopts the view that the faculæ and spots are due to the currents of hydrogen which forms the solar chromosphere. But to the ascending currents, the cause of which is unexplained, is attributed a descending current which, by penetrating amid the faculæ to the body of the sun, gives rise to a spot. The hydrogen thus drawn in reascends round about the funnel of the spot, and, by mingling with the ascending currents, effects a complete circulation. The author points out that these ideas are completely analogous to his own, and would be identical, had M. Spœrer studied the mechanical cause of this remarkable circulation, which is here attributed to the irregular velocities of the horizontal currents producing on the solar surface gyratory movements with a vertical descending axis like those of the terrestrial streams and atmosphere.—A comparative study of the actions of walking and running, together with the mechanism of the transition between these two movements, by MM. Marey and Demeny. In this paper, which complements the author's previous communications on animal kinematics, numerous differences are shown to exist between slow and rapid pace, the latter being characterised by moments of complete detachment from the ground and by other equally important features scarcely visible to the naked eye, but which are now clearly revealed by the chronophotographic and dynamographic processes. The paper is furnished with six diagrams illustrating the contrasts between both motions and the transitions from one to the other.—Considerations on the nervous system of the gastropods, by M. H. de Lacaze-Duthiers. In supplement to previous papers on several aberrant types of gasteropods, the author here continues his analysis of the facts connected with the central nervous system of these organisms. Special care is taken to distinguish between the groups of ganglia of primary importance from others which, notwithstanding their size and numbers, really play only a secondary part in the nervous system of the gasteropods.—Wheat culture at Wardrecques, Pas-de-Calais, and at Blasinghem, Department du Nord, in 1886, by MM. Porion and Dehérain. In continuation of previous reports of the results of experiments carried on for many years in the north-west of France, the authors here announced that the most profitable varieties of wheat are those which, besides yielding the largest returns, are best able to support strong manures without lodging. Preference above all is given to the square-eared variety (*blé à épi carré*), which they hope may be brought into general use in order to meet the growing competition of foreign growers.—Observations of Finlay's comet made at the Lyons Observatory (Brunner equatorial 0·16m.), by M. Gonnessiat.—Observations of the same comet made at the Observatory of Nice (Gautier equatorial), by M. Perrotin.—Note on the errors of division in Gambey's mural circle, by M. Périgaud. These errors being once clearly determined, the author considers that the Gambey circle with the new mercury bath allowing a continuous observation of the Nadir, may be advantageously used in astronomic researches where great precision is required.—On a question concerning the single points of plane algebraic curves, by M. E. B. Guccia.—On the glycerinate of soda, by M. de Forcrand. In this paper the author completes the study of the glycerinate of soda, begun by E. Letts in 1872, and subsequently prosecuted by M. Berthelot.—On the preparation of the sulphur of calcium with violet phosphorescences, by M. A. Verneuil. By the application of the principles laid down by M. E. Becquerel in his researches on phosphorescence, the author has succeeded in effecting the synthesis of this substance, which has been long known in commerce, but the preparation of which had hitherto remained a secret.—On the comparative volatility of the methylic compounds in the various families of the negative elements, by M. Louis Henry. In this paper the author restricts his inquiries to the monocarbonic derivatives, and more especially to the methylic derivatives. He finds that, at equal atomic weight, the diminution of volatility determined in methane by the substitution of a negative element for hydrogen, is all the greater the more this element is removed from hydrogen.—Law determining the position of the embryo in insects, by M. Paul Hallez. From his studies of *Hydrophilus piceus* and *Locusta viridissima*, the author arrives at a general law applicable to insects and probably also to other classes, which he thus formulates:—The cellule ovum is disposed in the same direction as the maternal organism, with a cephalic and a caudal pole, a right and a left side, a dorsal and ventral face coinciding with the corresponding faces of the embryo.—Contributions to the natural history of the Orthonectidæ, by M. R. Kœhler. During his researches on *Amphiura squamata* at the Zoological Laboratory at Cette, the author has found on these animals both male and female of the curious parasite, Rhopalura, already studied by Giard and Julin.—On the exhalations of carbonic acid in infectious diseases determined by aërial and non-aërial microbes, by M. S. Arloing.—Geological constitution of the district of Croix-Rousse (Lyons), by M. Fontannes. The tunnel 2400 metres long now in progress under the terrace between the Rhone and the Saone at Lyons has afforded an opportunity of studying the geological features of the district, which appears to consist mainly of Pliocene sands overlying gneiss with remains of *Mastodon arvernensis*, above which follow Pliocene alluvia with *Elephas meridionalis*, Quaternary alluvia, and Glacial deposits (moraines, loam, &c.).

OUR GUNS

WHENEVER attempts are made to manage scientific matters by means of committees failure is sure to result. Some of our Continental friends, the French especially, are fond of working in pairs, and excellent results have been arrived at by such means, but the method does not appear suitable to the English intellect, hence all our great achievements in science have been attained by single individuals. As soon as a committee gets to work, darkness seems to fall over the intellects of its members, and not only are the most absurd blunders perpetrated, and errors of judgment committed, but they are persevered in long after outsiders have detected and exposed them. We need only mention the Longridge wire-gun and the Moncreiff carriage as instances of the defective judgment which kept back the introduction of these useful and original inventions for some thirty years. But the blindness of the Ordnance Committee, or of the Unknown Being who is responsible for our guns, is still more curious and distressing with reference to the strains which guns must be constructed to withstand. We look in vain for any information on this head from the recent reports of committees or from the lectures of their inspired representatives, while such information as we have reveals the fact that, at the time when our new breech-loaders were designed, the knowledge of pressures which the Unknown Designers had was absolutely erroneous, and that the errors were of so elementary a character that it requires no special knowledge of the subject to detect them. If the indicator-diagrams of a steam-engine, and a statement of the work performed by it, were laid before, at any rate, the two civil members of the Ordnance Committee, with a request that the pressures in the cylinder should be investigated with a view to ascertaining whether they were correct, these gentlemen would, at once, compare the indicated power with the work done, and if the former were less than the latter they would, without hesitation, declare that the pressures said to have prevailed in the cylinder were too low. Now, attached to the official drawing of the first 10-inch breech-loading gun was a pressure-curve purporting to represent one-fourth the bursting pressure when firing a projectile of 500 lbs. weight, and imparting to it a muzzle velocity of 2100 feet per second. The mean pressure, measured from this curve, is 8·8 tons per square inch, the travel of the shot in the bore is 22 feet, hence the work done by the powder would be 15,205 foot-tons. The muzzle energy of the shot is a little more, namely, 15,284 foot-tons. But besides the energy communicated to the shot, the 300 lbs. weight of powder gases have to be set in motion, the friction of the gas checks has to be overcome, rotation has to be imparted to the shot, the atmosphere has to be displaced, and the aggregate of this work can be shown to amount to at least one-third of that required to drive out the shot, a fact which the pressures recorded in the experiments made with the *Thunderer* gun clearly proved. Colonel Maitland, in his lecture on our new guns at the United Service Institution in June 1884, rightly pointed out that the area bounded by the pressure-curve represented the work done in the bore; how is it, then, that it never occurred to any one on the Ordnance Committee to compare the work done with the effect produced? Such a comparison would have shown 20,400 foot-tons of work done by an indicator-diagram measuring only 15,205 foot-tons! The check pointed out should have been applied as a matter of common prudence, because it is notorious that then, as now, our direct knowledge of the pressure of powder gases in the bores of guns was very limited.

We are aware that it has been explained that the pressure-curve we have been discussing does not represent powder-pressures, but pressures one-fourth of those which would burst the gun; but such an explanation does not mend matters, for it reduces the factor of safety of the gun—already assumed at the dangerously low limit of four—to three, which no one, surely, would contend to be sufficient!

We are obliged to revert to the question, Why has not an actual pressure-curve been made public, and why did not the *Collingwood* Committee commence their report by showing that the 12-inch 43-ton gun was designed of sufficient strength? The answer, we are afraid, is that our gun-builders do not know what pressures they have to contend against, that our guns are being made by rule of thumb; in fact, their proportions are slowly arrived at by the costly method of trial and error.

Again, Colonel Maitland, in his lecture, gives a diagram showing, graphically, the pressure resulting from firing quick-burning, medium, and slow-burning powders. We must assume, the curves being given for the purpose of comparison, that they represent the effects of the same weights of powder burned under exactly similar conditions; therefore the areas of the figures bounded by the curves, as Colonel Maitland tells us, represent the work done in the gun, and measuring the areas of each curve up to only 14 calibres' length of bore we find that the slow-burning powder does more than twice the work of the medium-burning, and two and a half times that of the quick-burning powder! Surely Colonel Maitland would not wish us to draw such conclusions; and yet they are necessarily deduced from a diagram which must have represented the views of the Ordnance Committee only two years ago, and after Capt. Noble had shown, in his admirable lecture on "The Heat-Action of Explosives," delivered at the Institution of Civil Engineers, that the potential energy of all powders was very nearly the same; a view recently indorsed by Sir W. Armstrong, who stated that rather more of the slowest-burning powder was required to produce a given ballistic effect. We venture to say that, had the questions in review been under the control of a single, competent, fully-responsible man, the anomalies which we have pointed out could never have arisen, the aid of practical mathematicians would have been invoked, and the warnings of Sir W. Armstrong and others would not have been disregarded.

The public, no doubt, is weary of the constant discussion of past blunders, and the repeated allusions to them would be unjustifiable were it not for the vital bearing which these have on the future, and a most valuable result will be obtained if our efforts, and those of other writers, should be the means of destroying our

absurd system of administration altogether, or at any rate of dispelling the fatal complacency in which the Ordnance Department wraps itself, and which found a voice when Colonel Maitland declared two years ago "that our ballistic knowledge has long been fuller and more complete than that of any of the Continental authorities"!

But it is proverbially easy to find fault, especially with Government departments, though by no means so easy to propose practical remedies for defects of administration which force themselves so irresistibly upon the nation as do the shortcomings of our naval and military management. Fortunately, however, no great originality is required on the part of the would-be reformer. He has only to observe how great private firms manage their business, and carry on operations quite as extensive and complicated as any of the branches of Her Majesty's service. What private firm could exist, secure the confidence of its customers, or the soundness of its work, if its head were appointed for five years, and selected, not because he had received special training in the business which he is about to manage, but had done good service in some other situation for which he had been trained; or, worse still, if the selection were made because the man selected was a good fellow and on the best of terms with all the members of the firm! Has any great firm ever started as a company? Has not every one of them owed its origin to the personal qualities of some one man, and those that have survived the death of their founder, have been carried on by men of distinguished ability selected usually by him. We do not speak of enterprises requiring so little originality as railway, gas, or water companies, but even in them the chairman rises by a species of natural selection to a position of prominence, the natural homage due to a master mind. Would any sane man propose, for a moment, that the chairmen of such companies should be changed every five years, and farther, that in order that they might suffer no loss they should exchange offices, that is, the railway chairman, at the expiration of his term, should become chairman of the gas or water company, and so on?

Yet this is precisely the way in which our dockyards and arsenals are managed. Officers, most of them most estimable and excellent gentlemen, who happen to be in favour with the superior powers, receive these desirable appointments, and often travel from one to another till they are obliged to retire from the service altogether. They would be more than human if they refused the offers made to them, and it is unreasonable for the public to cover them with abuse on account of shortcomings which are due to the system, and not to the individuals. We cannot, for a moment, admit that any of the committees are corrupt in the slightest degree, directly or indirectly, or that they have not done their best to carry out the work intrusted to them; neither are we disappointed with the results of our absurd organisation, any more than we should be with the misfits which would result if we insisted on our tailor becoming our bootmaker also.

Take the case of the Ordnance Committee. It is composed of officers who, including the President, are being continually changed, and it also numbers two apparently permanent civil members. Not one of these gentlemen has been brought up to the business of steel-making or gun manufacture, not one of them has made himself a name in the branch of manufacture and metallurgy which the Committee directs, not one of them would be competent to go abroad and start a steel-works and gun factory unaided by the contractors and subordinate experts about them—how can they be competent to deal either with the complicated theories or the practical details of gun manufacture? and when failure occurs, who is to blame?

Judging by Colonel Maitland's lecture and Sir F. Bramwell's expositions, the Committee, as a body, and as individuals, are not only satisfied but even complacent, for they find that other nations are in almost as bad a muddle as we are ourselves. It is perfectly obvious that there must be individual responsibility. The head of each department must be a permanent officer directly responsible for the design and execution of such things as the military or naval forces require, and these heads should be selected from the most able men to be found within or outside the services, men who have already achieved a reputation in the special departments for which they are required.

And there are precedents for this. The Post Office;—can anything exceed the admirable manner in which that branch of administration works, and keeps in the forefront of progress? It is needless to say that it is not worked by shifting committees. Or, take the steam department of the Admiralty. We never hear of serious complaints of the main engines or the countless subordinate machines of our war-ships; our Navy is ahead of all others in respect of adapting every useful invention, every scientific appliance; but then Mr. Wright is a permanent chief, and he is not hampered by a committee composed, shall we say, of carpenters appointed for short terms of office. And yet the changes wrought in Mr. Wright's department during his long term of office are more extensive in kind and much more varied in detail than anything the Ordnance Department have had to contend with. The steam-engine has been completely altered, surface condensation has been introduced, the steam-pressure has been increased eight-fold, compound and triple expansion has been introduced, the whole system of torpedo warfare has come into being with all its complicated appliances, the electric light has been adopted, and in addition the design and supervision of the Dockyard machinery has fallen to his share. The public never hears of Mr. Wright: had we not mentioned his name, most of our readers would have been ignorant as to who was the meritorious officer to whom we were referring; his very virtues have been the cause of his obscurity; his is not an heroic part, and he has never drawn public attention to himself by making a mess of anything.

And next, let us look abroad. We have no hesitation in stating that the most successful gun factory in the world are the Abouchoff Works near St. Petersburg. That establishment, since 1866, has been under the direct personal control of Admiral Kolokolzoff, and during that period the guns turned out have not varied either in design or material; they have been increased in length and constructed to produce higher muzzle energy; but it

is an absolute fact that the projectiles which fit the guns of 1866 can be fired from the guns of to-day, and *vice versâ*. None of the Abouchoff guns have ever burst or injured a single man! The Committee on the *Collingwood* accident ascribe the disaster in part to the unequal composition of the material. Admiral Kolokolzoff provides against the possibility of this by using nothing but crucible steel. His casting-house contains about 2000 crucibles; each holds a small charge of steel, the composition of which is determined with the utmost care and exactness. The consequence is that his material is absolutely uniform, and, in addition, he is the only man that has adopted Whitworth's method of fluid compression. He does not use crucible steel because he has no other means of casting: he has Bessemer converters and Siemens-Martin furnaces; but for the highest-class work he prefers the crucible metal, because of its necessary uniformity when prepared with proper care. Had we had a man of the Admiral's capacity permanently at the head of our Gun Factory, had we subsidised any important steel-works as liberally as the Elswick firm has been assisted, we could also, twenty years ago, have had ingots of 40 tons weight of crucible steel of any quality desired. The Abouchoff works began to make 12-inch guns about the same time as we did, but their gun of the same proportions as those of the *Collingwood* weighs 50½ tons against the 43 tons of our discredited weapon. Our amended guns will weigh the same as the Russian. How is this to be accounted for, if we be, as Colonel Maitland asserts, far ahead of our neighbours in the science of gunnery?

Let us now contrast the Russian record with the history of our own guns. Sir William Armstrong introduced what he, in his address to his shareholders, calls, with some pride, his own gun—our first breech-loader. It was a built-up gun, upon the principles advocated by Mr. Mallet in his work on artillery in 1856, and the breech mechanism was a close imitation of that of the guns on board the Chinese junk which was moored off Essex Street during the Exhibition of 1851. At that time the Broadwell ring, or, rather, gas-check, such as we know it applied to muzzle-loaders, had been used at Woolwich, but had probably been forgotten; at least it was not applied to the Armstrong breech mechanism, which failed from its avowed danger when applied to the larger calibres of guns. We then gave up breech-loading and reverted to muzzle-loading, and finally we have come back to breech-loading, and adopted steel some twenty-five years after the Russians had completely solved whatever difficulties there may have been in the process of using it. In muzzle-loaders we revert to the gas-check, and so we have at least three classes of projectiles in use instead of one only. How is it that we have got into all this confusion? The only possible answer is that it is caused by our absurd system of having no permanent responsible scientifically educated officer at the head of each department of the Arsenal. The newly appointed chief knows nothing of what his predecessor did or what his experiences had been, for experience cannot be readily communicated from one man to another; he is, in fact, not a chief, but, for more than half his time, the slave of his permanent subordinates.

HAINAN AND ITS PEOPLE

Ling-Nam, or Interior Views of Southern China, including Explorations in the hitherto untraversed Island of Hainan. By B. C. Henry, A.M. (London: S. W. Partridge and Co., 1886.)

PORTIONS of this book have already appeared from time to time in the two magazines in the English language published in China, the *China Review* and the *Chinese Recorder*, but they well deserved the more permanent book form, for the author, like many other missionaries, has travelled widely in parts of China which are rarely visited by Europeans. Mr. Henry, too, writes from a full mind; he has made the most of his great opportunities, and accordingly he has contributed here a very real and solid addition to our knowledge of the Middle Kingdom. In reading it we are constantly reminded of a work written a good many years ago by another missionary, which has now almost attained the dignity of a classic, viz. Dr. Williamson's "Journeys in North China"; both are of the same useful, substantial kind, and for a long time to come both will have to be referred to for information in regard to the respective districts with which they deal. Mr. Henry refers solely to Southern China, as the name *Ling-Nam* ("South of the Ridge") implies, and to the Kwangtung or Canton province. He describes various journeys through the central and northern parts of this large and populous province, along the principal streams. As we read o town after town with populations of 100,000 and over, we begin to understand how populous China is. But then, with the exception of the valley of the Yangtsze, the two great southern provinces of Kwangtung and Kwangsi are the most thickly peopled of the whole empire. Even those who have travelled in parts of the Canton province will be surprised to learn from Mr. Henry of the magnificent scenery of the north and north-west. The idea of the passing traveller in and around Canton and the neighbouring cities is that the whole province is a vast plain in a high state of cultivation; but in the upper courses of the tributaries of the West River Mr. Henry found scenes worthy of the wildest mountain regions. Here also, on the borders of Hunan, he came in contact with one of those tribes which are found like scattered fragments over the whole of China south of the Yangtsze—amongst, but not of, the Chinese, with their own communities living generally in fastnesses amongst the mountains, preserving in a great measure their ancient habits, and but slightly contaminated by the proximity of their Chinese conquerors. Their name is legion, and they are sure to furnish abundance of work for ethnologists in the future. In the present instance the people are called the Iu, and are described by Mr. Henry as lower in stature than the Chinese, with a similar complexion, although some are almost copper-coloured. They do not shave the head, but wear the hair coiled up behind, men and women having long hair. They wear immense silver earrings and necklets, while the hair is decorated with ornaments made of the pith of the wood-oil tree and cocks' feathers. Their territory is forbidden ground to the European, the Chinese taking care that the restriction is rigorously enforced. The meagre Chinese accounts of this people

add little to our knowledge of them; but it appears that they have no written language, although a few understand Chinese. Their language is distinct from any Chinese dialect. Beyond these few details nothing is known of the Iu, and they and their country appear destined to remain a mystery for some years to come.

But beyond question the most interesting and valuable chapters in the book are those dealing with the island of Hainan. This has been hitherto in great measure a *terra incognita*. The late Mr. Swinhoe succeeded in going a few days' journey from the coast, and vessels occasionally touched at one of the ports. But it was not until a few years ago that its position was properly settled; before that time it was twelve miles out on all the charts. Mr. Henry, with a Danish gentleman who had already made a circuit of Hainan on foot, travelled into the heart of the island, and making a long detour returned to the port of Hoihow on the north. He thus travelled through a considerable part of the mountainous region in the centre, which is the abode of the Lis, or aboriginal population, and had ample opportunity for studying their habits. The information given in this book about the island and its people is, as far as we know, the first detailed and definite account published in any European language. The whole northern half of the island he describes as a plain, level to a great extent, but mostly undulating, and broken in a few places by isolated hills and low ridges. The central and southern portions are mountainous, the highest elevation being reached in ranges called the Five-Finger and Li-Mother ranges, from which all the larger streams take their rise. The flora of the island, though but slightly investigated, is known to be of great variety and interest. Mr. Henry noticed about 100 species of plants which he recognised as well known, while he brought back 200 species which are now in process of determination. From what is now known, the flora seems more nearly allied to that of the islands of the south than to that of the adjacent mainland. The number and variety of Hainan birds is suprising. Mr. Swinhoe noted 172 species, 19 of which proved new to science, and were first described by him; but as his journey was only of a few weeks' duration, and chiefly along the coast, it is probable that many new discoveries in ornithology will be made when the interior is better known. Of the mammals even less is known, and the variety of fish around the coast is endless. The meteorology, too, is noteworthy. Hainan is the home of the typhoon, and earthquakes are of frequent occurrence. In the latter case the axis of disturbance runs directly across the island from one side to the other. Of the people Mr. Henry is able to give us much more information. The Chinese immigrants have peopled the coast opposite the mainland, and all the low-lying lands up to the base of the hills, which latter are inhabited by the Lis. But between the two is a people speaking a Loi dialect, the origin of which is unknown. They are like the Chinese in many respects: they wear the same dress, live in the same kind of houses, eat the same food, and intermarry freely with them, but they hold to their peculiar dialect with remarkable persistence. There is a theory that these people are descendants of Miao-tsze, brought ages ago from the highlands of Southern China to act as mediators between the Chinese and the aborigines of Hainan. How far they resemble any tribe on the mainland remains to be determined, but they are wholly distinct in physique, language, and customs from any of the Li tribes. The ubiquitous Hakkas from Canton have also established themselves in Hainan, pursuing agriculture under the most forbidding circumstances, and converting the jungle into cultivated fields with their usual tenacity and success. But the main interest of the Hainan portion of the book centres around the Lis. Here, as everywhere else that they have come into contact with aborigines, the Chinese have adopted the simple classification of "tame" and "wild," "ripe" or "green," to distinguish those who have succumbed to Chinese influence and those who have not They wear the hair twisted into a knot on the top of their heads. The women are all tattooed with blue lines over the face. The process of tattooing is very simple. An incision is made with a sharp knife to the shape of the pattern given; and, while fresh, ordinary Chinese ink is introduced, which gives a blue tinge, and in a few days the wound begins to heal. The Chinese say that the same pattern is preserved for generations in the same family, not the slightest variation being allowed, lest the husband's ancestors should not recognise the wife after death. In a Chinese account of the Lis, translated by Mr. Henry, it is said that their custom is not to cry when their parents die, but to swallow quantities of raw meat, which is their mode of expressing great grief,—a curious circumstance, which possibly may be accounted for by the statement made in the same account, that the Lis originally belonged to a race of birds and beasts, and that being derived from an egg they remained impervious to Chinese civilisation. However this may be, Mr. Henry found them a simple, kindly, hospitable people, who appeared to think nothing too much trouble when assisting the stranger. No idols, or other religious symbols, or indeed trace of a religion at all, was found amongst them, although the traveller looked carefully for them. A curious custom among them is for the young people to have authority in the house, and every question of food, lodging, or purchase of articles is referred to them. The father and mother appear to efface themselves inside the house. At meals the whole family is united. They greet a guest by extending the arms, placing the open hands with the finger-tips touching, or nearly so, and draw them inwards with an inviting motion. They bid farewell in a similarly graceful fashion, extending the open hands with the palms upwards, and slightly inclined outwards, in a movement as if handing one on his way. Their features are rather square, the nose not being so flat as that of the Chinese, and the eyes of a different type. No sign of graves was seen anywhere, and all inquiries failed to elicit any intelligible account of what they do with their dead. The substance of all that the travellers could learn was that they place the body without a coffin in any secluded spot, taking care to replace the earth, and cover it over so that it may not be recognised. They are free from many of the superstitious and idolatrous practices of the Chinese; they have no ancestral worship, and no knowledge of geomancy. They seem to be divided into fifteen or sixteen tribes, which are known under different names, and differ more or less in dress, language, and customs, but all evidently belonging to one homogeneous race, bound together by common ties, and as a rule living on friendly

terms with each other. Mr. Henry thinks they are probably of Malay origin, but his argument, based on the names by which they call themselves, appears somewhat weak. It is more probable that we shall know nothing of the ethnology of the Lis until that of the Lolos, the Miaous, Ius, and many other tribes of Southern and South-Western China and Tonquin, has been studied. Whether the Lis have a common origin with one or all of these, or with the aborigines of Formosa, must for the present remain in the region of conjecture. But there can be no manner of doubt that, in the words of Mr. Henry, Hainan promises much of interest to the traveller and scientific investigator, in its striking natural features, in its imperfectly known flora and fauna, and in the questions that arise as to the race, religion, and probable destiny of its aboriginal people.

GIGLIOLI'S "AVIFAUNA ITALICA"

Avifauna Italica. Elenco delle specie di uccelli stationarie o di passaggio in Italia, colla loro sinonimia vulgare, e con notizie piu specialmente intorno alle migrazioni ed alla nidificazione. Compilato dal Dottore Enrico Hillyer Giglioli, &c. 8vo, pp. 626. (Firenze, 1886.)

A SHORT time ago (NATURE, June 24, p. 168) we noticed the new "Check-List" of North American birds issued by the American Ornithologists' Union, and took occasion to refer to the corresponding "List of British Birds" compiled by a Committee of the British Ornithologists' Union, and published by that Association in 1883. We have now before us a copy of a similar publication upon the birds of Italy, prepared, however, under somewhat different circumstances.

At the International Ornithological Congress held at Vienna in 1884, which was attended by delegates from nearly all the civilised nations of the world (with the strange exception of Great Britain !), Italy was worthily represented by Prof. E. H. Giglioli, of Florence, well known as one of the most learned and enterprising zoologists of that country, and for the excellent series of Italian vertebrates which he has collected together in the museum under his charge. In consequence of the recommendations contained in the report presented to the Italian Government on the results arrived at by the Congress, it was determined to constitute an "Ornithological Office" in Italy under the Ministry of Agriculture, and Prof. Giglioli was made Director of the new Department. In compliance with the resolution passed at the International Ornithological Congress, one of the new Director's first tasks was the compilation of a standard list of Italian birds, or "Avifauna Italica," as it is here shortly termed.

In preparing their various lists of native birds, the delegates at the Congress were invited to follow as a model the catalogue of Austro-Hungarian birds, lately issued by Messrs. v. Tchusi zu Schmidhoffer and v. Homeyer. But Prof. Giglioli could not altogether acquiesce in this recommendation, and, perhaps wisely, preferred to adopt the systematic classification already employed for his series of birds in the collection of Italian vertebrates at Florence already spoken of, which is in fact by far the most nearly complete collection of the kind existing in the Italian kingdom. Besides the correct scientific appellation of each bird, and what is considered as its standard Italian name, Prof. Giglioli has also taken great pains to give all the vernacular terms by which each species is known in the many and various Italian dialects. These are in some cases very numerous, as will be seen on reference to such species as *Lanius excubitor* and *Merops apiaster*, and, although of less interest to foreign naturalists, will make the list of greater value to the native student of Italian birds—whose assistance is specially required in ascertaining many yet unknown particulars concerning the range, times of migration, and mode of nesting of the various species.

As regards the limits of the Italian avifauna, it would seem that Prof. Giglioli is an "Irredentist" of the most extreme type. Not only does he include Corsica and Malta within the Italian zoological region, for which, no doubt, he has every show of reason, but also the Trentino, Istria, and Dalmatia. It is difficult to understand why the line should be drawn at Dalmatia, or why it should not also just as well include Montenegro, Epirus, Greece, and even Macedonia ! This so-called "Italian Region" is divided by Prof. Giglioli into three provinces, namely, a Northern Continental, and a Southern Continental Province, separated from each other by the line of the Apennines, and an Insular Province, consisting of Sardinia, Sicily, and the Maltese Islands.

Not only has our author been very liberal in the extent of country assigned to the Italian Ornis, but, in our opinion, he has also somewhat unduly increased the number of species included in the avifauna by the admission of some of very doubtful authority. The occurrence of *Aquila nipalensis* within Italian limits, for example, does not seem to be supported by any certain evidence. The same may be said of *Caprimulgus asiaticus*, *Chelidon cashmiriensis* (!), *Cotile obsoleta*, *Dendrocygna javanica*, and at least half a dozen other species in Dr. Giglioli's list. It would seem, therefore, that the number of species (443) assigned to the "Avifauna Italica" in the present work may have to be slightly diminished, although, on the other hand, future researches will doubtless result in the discovery of many additions to the series of occasional visitants.

Strange to say, one of the most recent and noteworthy additions to the list of permanently resident Italian birds has been made by an English ornithologist. In 1883 Mr. J. Whitehead discovered in the pine-forests of Central Corsica, a nuthatch perfectly distinct from every other known European species, and for the nearest ally of which we must go to Asia Minor. This nuthatch has been named after its discoverer, *Sitta Whiteheadi*. It is quite possible, therefore, that not merely more stragglers from other parts of Europe, but even new endemic species, may still have to be added to the Italian List.

After finishing his general catalogue, Prof. Giglioli goes into a general discussion of the Italian avifauna, and gives the number and names of the various categories into which the 443 species assigned to it may be divided. The permanent residents are stated to be 207 in number, the summer visitants to be 69, and the winter visitants 36. Those of regular passage are only 9 in number ; those of irregular passage, 8. Besides these, 28 are set down as

of irregular appearance, 80 as stragglers, and 6 as doubtful. Two "ornithological calendars," one giving the times of "migration" and the other those of "nidification," add considerably to the value of this useful work, which must not only of necessity be in the hands of every Italian ornithologist, but which every student of the European Ornis, or of any constituent parts, should have for reference. We trust that the good example thus set by England, America, and Italy will lead to the publication of other similar hand-books.

OUR BOOK SHELF

The Law of Storms, considered practically. By W. H. Rosser. Second Edition. (London: Norie and Wilson, 1886.)

WE welcome with much pleasuie the second edition of this useful little work on storms practically considered. The first edition, briefly noticed by us at the time (vol. xiv. p. 504) appeared ten years ago. Since then the researches of meteorologists have materially advanced the science, notably in establishing on a firmer basis the law of the in-moving spiral circulation of the wind in cyclones, and defining with some exactness the limits of variation of the angle of inclination of the winds as they blow inwards toward the centre of storms. In this view especially the last part of the work has been recast, recent investigations being summarised with no little ability, and the results thereafter applied to navigation. The book, which is professedly a practical one, is specially and admirably adapted to give seamen the best available information in handling their ships in storms.

Ueber Manatherium delheidi, eine Sirene aus dem Oligocän Belgiens. Von Dr. Clemens Hartlaub. *Zool. Jahrb.*, vol. i. (1886).

DR. CLEMENS HARTLAUB'S excellent contributions to our knowledge of the recent Sirenians have lately been noticed in these columns (July 8, p. 214). We have now before us his essay on an extinct form of the same peculiar group of mammals. The luxuriance of fossil forms of the Oligocene of Belgium is well known to all zoologists. Upon materials gathered from the Superior Rupelian beds of Hoboken, near Antwerp, which have already produced remains of *Crassitherium* and *Halitherium*, Dr. Hartlaub founds a new genus of Sirenians, nearly allied to the living Manatee, which he proposes to call *Manatherium*. Its dentition, so far as it is at present known to us, does not materially differ from that of *Manatus*, of which, indeed, it may have been the immediate progenitor; and the necessity for its generic separation from its modern representative is perhaps not altogether evident. The species is named *Manatherium delheidi*, from M. E. Delheid, in whose cabinet of Belgian fossils the remains upon which it is based are contained. Fossil species of true *Manatus* have been described by Leidy and other authors in America, and M. Filhol has assigned some African remains to the same genus. But *Manatherium delheidi* is at present the only European form described as belonging to this exact type of the Sirenians.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

The Tangent Scale in a Galvanometer

ON account of the correspondence which has recently taken place in this and other journals regarding the use of the tangent scale in a galvanometer, when the plane of the coil makes an angle with the direction of the force in the magnetic field, the following extract from Sir William Thomson's patent, No. 4617 of 1883, and the accompanying remarks, may clear up some of the points that have been raised:—

"In using this instrument I sometimes cause the zero to be at one end of the scale, so that, when the potential is at the prescribed definite amount, the pointer is at the centre mark of the scale of tangents. The deflections are thus more easily observed, on account of the large size of the divisions."

This extract is quite explicit as to taking the zero at one end of the scale, and it is abundantly evident, from the text of the patent and from the illustrative drawings, that the scale referred to is a tangent scale. The essential feature in this use of the tangent scale is that the strength of the current is proportional to the difference between the tangents of the angle corresponding to zero and that corresponding to the deflection due to the current.

The total length of the scale, as shown in the patent already referred to, and used in this Laboratory for over two years, is 120°. Lately, however, the length of the scale has, with considerable advantage, been increased to 147°·8, thus giving twice the sensibility obtainable with the 120° scale.

As regards Prof. Carey Foster's letter to NATURE of October 7 (p. 546), a tangent galvanometer arranged to use the tangent scale in this manner is essentially adapted to measure currents which flow through its own coil in one direction only, but in these instruments, as designed by Sir William Thomson, the necessary accuracy is secured by the following procedure. The index (which has a range of about 95° on each side the middle point of the tangent scale) is caused to point to a mark exactly 90° from the middle point of the scale, and the relative positions of the coil and the scale are then adjusted, so that, when the index points to the 90° mark, the strongest current which can be safely sent through the coil produces no sensible deflection.

On the Connection between Chemical Constitution and Physiological Action

IN the address delivered by Dr. Brunton on this subject before the Section of Therapeutics and Pharmacology at the last meeting of the British Medical Association, a copy of which was published in NATURE, August 19, p. 375, he observes, in alluding to the adoption of more scientific methods in pharmacology:—"This may be said to have begun about twenty years ago, when the researches which my predecessor in this office, Dr. Fraser, made with Prof. Crum Brown upon the connection between physiological action and chemical constitution inaugurated a new era in pharmacology. . . . We might first date the beginning of this age from Blake's attempts to show that a connection exists between the forms in which the various bodies crystallise, and the mode in which they act on an animal body. . . . Nevertheless, I think we may fairly say that it was the experiments of Crum Brown and Fraser which fairly started pharmacology in the new direction in which it has since been steadily advancing." Now it can, I think, be shown that in these remarks Dr. Brunton has not only misunderstood the scope of my experiments, but that he has been led into error on account of his having no definite idea of the meaning of the term chemical constitution, which he has evidently confounded with that of chemical composition. The same confusion of these terms is not only apparent all through the address, but is also found in the paper on the subject by himself and Dr. Cash, published in the *Transactions* of the Royal Society, 1884.

The term chemical composition is well understood, but the meaning of the term chemical constitution is not so well defined. Perhaps the difference between the two terms may be pointed out in the shortest space by an example. If we take the salts of iron, for instance, we know that the salts of the protoxide have a chemical constitution analogous to the other members of the magnesian group with which they are isomorphous, and that this resemblance in constitution connotes not merely that they crystallise in analogous forms, as Dr. Brunton seems to imagine, but also that they form many analogous chemical compounds which resemble those of the other members of the same group more closely than the compounds of any other group. By the addition of oxygen to the protoxide, not only is its chemical composition changed from FeO to

Fe_2O_3, but at the same time a base is formed, the compounds of which are totally different from those of the ferrous oxide, but which resemble in their chemical properties the salts of alumina, Al_2O_3, with which they are isomorphous. Here there is evidently a change, not merely of composition, but of constitution; the addition of oxygen has not only altered the relative weight of the constituents, but has completely changed the structure of the molecule in a definite direction, and impressed on it a constitution analogous to that of the molecule, Al_2O_3, with which it is isomorphous. Now, when I had shown that this change in the constitution of the salts of iron was attended by a marked change in their physiological action, when I had proved that the physiological action of the ferrous salts was analogous to that of the salts of the other members of the magnesian group, which they resemble in chemical constitution, and that the physiological action of the ferric salts was analogous to that of the salts of alumina with which they are isomorphous, and when it was proved that an analogous connection existed between the chemical constitution and physiological action of the compounds of the elements of all the more important isomorphous groups, I think nothing but a complete misapprehension of the meaning of the terms chemical constitution and isomorphism could have led Dr. Brunton to allude to my researches as an "*attempt to show that a connection exists between the form in which various bodies crystallise and the mode in which they act on an animal body.*" The same error as regards the meaning of the term chemical constitution has led Dr. Brunton to fail to comprehend the bearing of the experiments of Crum Brown and Fraser on the question, on which, in fact, they throw no light, although evidently regarded by him as a beacon for subsequent observers. These gentlemen found that by the addition of an ethyl or methyl molecule to strychnia its physiological action was profoundly modified, and concluded that this was owing to the chemical constitution of the substance being changed. As they worked with a reagent, strychnine, of the chemical constitution of which we are still ignorant, it was impossible for them to know if the addition of an ethyl or methyl group had made any change in its chemical constitution. The probabilities are that no such change had taken place, as the new compounds were addition and not substitution compounds. It is not merely for asserting a claim to priority that I make this communication, although I think *suum cuique* a very good rule; but I wish to point out the causes which in my opinion are not only retarding the progress of physiology in this direction, but which are tending to throw it back to where it was before the publication of my earlier experiments nearly fifty years ago.

October 6 JAMES BLAKE

Relation of Coal-Dust to Explosions in Coal-Mines

IT is a stubborn and grievous fact that the loss of life by explosions in coal-mines has risen in the last decade, although the number of explosions has fallen. This points clearly to some essential defect in the remedies adopted. The remedies in use apply apparently to one class of explosions only, hence the decrease in the number of explosions. But, unhappily, there are many to which they do not apply, and those the worst; hence the larger number of lives lost. Some research, which has much engaged me of late, and which I hope soon to make public, has led to the conclusion that possibly the reason of this is about to be, or is even already, detected.

Many, well competent to judge, have thought that too much attention has been given to *gas*, and too little to *dust*. This is a growing conviction, both in Germany and in England, and of late years the dust has had considerable attention. A work, recently published (September 1886) by Messrs. W. N. and J. B. Atkinson (Government Inspectors of Mines), entitled "Explosions in Coal-Mines," strives, and I think fully succeeds in establishing that many of the most disastrous colliery explosions in the last six years have been practically "*dust explosions.*" My conclusion, from certain simple physical and chemical experiments, and from a most careful microscopic examination of coal-dust from various seams worked in this field, is that the Messrs. Atkinsons' view is right, and, moreover, that the attention hitherto given to coal-dust has not only been useless, but absolutely pernicious, since it has lulled into a state of false security.

I have been down several typical coal-pits in this district (the Durham field), such as Seaham, Murton, Silksworth, Pelton, &c., and in some of them I have seen the water-pipes along the main haulage roads supplied at convenient distances with stop-cocks, and have found the dust on such roads so damp as to be rendered harmless, if it had not been so already, but the fine dust which coats the upper faces of the roof-timbers was there untouched, lying often to the depth of half an inch. Now, the *bottom dust*, as we may call the former, I am prepared to prove is almost if not quite universally harmless; and the *upper dust*, as we may call the latter, I am equally prepared to prove is in the highest degree dangerous, and especially a certain portion of it, which I propose to call "*flocculent dust.*" Lastly, I claim to be able to establish that the main source of the really dangerous dust is that portion of the coal called variously "dant," "mother of coal," and "mineral charcoal." The upper, and especially the flocculent dust, possesses physical and chemical properties wanting, or existing in the most shadowy form, in the bottom dust; and the microscopical aspect emphasises these differences, as well as shows the relation of the former to what is very appropriately called "mineral charcoal."

It would pass beyond the limits of a letter to enter into particulars, but the observations and opinions of others may be hereby evoked, and this good work of saving life and property be materially furthered by your kindly admission of this letter to your pages. I will now only add that this ordinary upper dust and this flocculent dust removed, or rendered innocuous, it is my firm conviction that the number of explosions will rapidly fall, and also the loss of life be greatly reduced. This is the goal of my effort. Some practical men may indicate means, and perhaps I, who am a student, may be permitted to suggest that keeping the ventilating air-current saturated with aqueous vapour, rather than direct watering, would, if it be practicable, both lessen the amount of this dangerous dust, and also facilitate its removal. Bede College, Durham, October 12

Volcanic Ash from New Zealand

A SAMPLE of the ash ejected during the recent eruption in New Zealand has just reached me through the kindness of Mr. W. Ferguson, Harbour Engineer, Wellington. It was collected sixty miles from the seat of the volcano.

The ash is of a gray colour, of a somewhat darker shade than that from Krakatão. The dark-coloured constituents of the New Zealand ash consist principally of black scoriaceous fragments and ferruginous particles of indefinite character; those of Krakatão consist mainly of magnetite and hypersthene, well defined. The following minerals are contained in the New Zealand ash:—

Plagioclase Feldspar, very fragmentary, limpid, showing polysynthetic striations in the polariscope, and sometimes medial twinning line. The few well-formed crystals observed recall the tabular forms from Krakatão (described in my paper, *Proc. Roy. Dublin Soc.*, vol. iv. p. 291). There is a notable absence of the cellular vesicular covering observed in the Krakatão feldspar, and so suggestive of the pulverisation of a ready-formed pumice.

Hornblende, in elongated prisms, sometimes fibrous longitudinally or striated; colour dark green, pleochroic green longitudinally to brown; extinction makes a small angle, less than 15°, with the prism axis; occurs occasionally included in the feldspars. It is scarce.

Biotite and a golden-coloured mica are common in well-formed crystals of hexagonal outline, remaining dark between crossed Nicols.

Iron Pyrites, free and in embedded grains; striated pale yellow octahedral forms. Scarce.

Magnetite, in lustrous black octahedral forms. Not abundant.

Sulphur, in small broken pale-yellow fragments; burns with the characteristic smell, held over a lamp. Scarce.

Glass, remaining dark between crossed Nicols; variously coloured and often containing crystallites arranged fluxionally. Common.

Of these minerals, mica, hornblende, and sulphur are, so far as my observations go, not present in the Krakatão ash. Comparing it with samples from Krakatão gathered at a comparable distance from the scene of eruption, the New Zealand ash suggests a more hastily formed material, the minerals in common being less perfectly developed in the New Zealand ash. I have not noticed as yet in this ash the hypersthene conspicuous in that of Krakatão. There are some organic remains, calcareous fragments of shells. J. JOLY

Physical Laboratory, Trinity College, Dublin, October 18

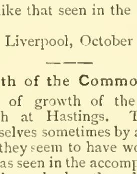
An Abnormal Starfish

A FEW weeks ago I dredged, off the north end of Arran, an interesting specimen of *Porania pulvillus*, Gray (= *Goniaster templetoni*, Forb.). It is rather more than 5 cm. in diameter, and one of the five short rays (that opposite to the madreporite), when viewed from the aboral surface, is seen to be distinctly bifurcated about 1 cm. from its termination. On examining the oral surface, it is found that the ambulacral groove of the abnormal ray divides into two branches at a distance of 2 cm. from the edge of the mouth. One of these branches runs along one of the forks of the ray to its extremity without further complication, but the other branch, belonging to the second fork, divides again 2 mm. from the first bifurcation, so as to form two tracts, which unite with one another 3 mm. further on, thus inclosing a small piece of the ordinary integument in an ambulacral area. Finally, this ambulacral area divides once more close to the tip of the ray. Consequently, there are three bifurcations of the ambulacral area in a space of not more than 1 cm. in length. As there are no signs of injury or disease on the specimen, the abnormal condition seems to have been caused by a tendency to dichotomous division like that seen in the rays of Crinoids and of the Astrophytidæ. W. A. HERDMAN

University College, Liverpool, October 9

Peculiar Growth of the Common Acorn-Shell

A PECULIAR mode of growth of the common acorn-shell (*Balanus*) is met with at Hastings. These crustaceans are known to attach themselves sometimes by a shelly basis to rocks, &c. In this instance they seem to have worked together to form a common shelly tube, as seen in the accompanying life-size figure; still overcrowded, they have also lengthened their outer valves, thus spreading themselves out like the umbels of certain plants, as



many as fifty individuals being sometimes borne on one of these tubes. The columns supporting the pier are completely covered with them up to high-water mark. Except a comparative few of a later generation which—as will be seen in the figure—have attached themselves to the tube, and are in the normal condition, they all appeared to be dead, but of this I am not certain. Lunar Rainbow—Halo round the Sun in Connection with the Storm of October 15 and 16

ON the evening of the 9th there was a good lunar rainbow between 7 and 8 p.m. I have not seen one for some years, although about twenty years ago in one winter I saw seven or nine, I forget exactly which.

On the 14th, while coming home between 3 and 4 p.m., I saw a remarkable halo round the sun. I had intended making a sketch of it, but when I arrived there was pressing business, and when I was disengaged it was gone.

The halo was nearly a complete circle, but somewhat pressed in at the sides. Inside, there was a dark mass with a hard defined edge, with the least trace of faint mock suns at the left and right hand lower edges of the circle; outside, the sky was remarkably clear, of a greenish-blue colour. The evening and up to midnight was very hot, which was suceeeded first by heavy rain, then wind that lasted for over forty-two hours; during this time there was considerable heat; afterwards for about six hours it was fine, to be succeeded by heavy rain, and cold; this afternoon (October 17) is fine, with half a gale blowing. I should have mentioned that after the halo the aneroid went down as low as 28·3.

Ramelton, co. Galway J. H. KINAHAN

Mimicry in Snakes

I BEG to remark with reference to Mr. W. Hammond Tooke's letter on mimicry in snakes (NATURE, October 7, p. 547) that I stated a case of mimicry in snakes in the year 1869 (see also *Proceedings* of the Zoological Society, 1870, p. 368), and that I recently published a short paper on Adeniophis, which again treats the case. A. B. MEYER

October 9

The Gale

IT may be worth mentioning as a curious coincidence that three of the most violent gales of recent times occurred on very nearly the same date of the year, namely:—

Sunday, October 14, 1877.
Saturday, October 14, 1881.
Friday, October 15, 1886.

The first of these was the most destructive in its effects as regards this district. W. F. DENNING

Bristol, October 16

Adam's Peak

WITH reference to the "Adam's Peak shadow" I may perhaps mention the following fact:—While at Saas Fee (Canton Valais, Switzerland) this summer, we noticed more than once that the shadows of the Dom and its neighbours stood out clearly defined in the atmosphere. They were manifestly thrown on the cloud and mist that were suspended in the air at the time. The phenomenon was in this case witnessed from below.

Cheltenham, October W. L.

THE MARINE BIOLOGICAL STATION OF BANYULS-SUR-MER

YESTERDAY I had the pleasure of visiting the "Laboratoire Arago," or Marine Biological Station of Banyuls, being the second institution of this sort founded by M. Lacaze-Duthiers in connection with the College of the Sorbonne. I found it in full working order, the session, which lasts here from October to June, having just commenced. The building is placed at the western point of the little bay on which the fishing-village of Banyuls is situated, just beyond the Établissement des Bains, and consists of three stories. The ground floor is one large *salle*, containing basins which are abundantly stocked with marine animals, and is open to the public for inspection as an "aquarium." The lighting of these basins appeared to me to be particularly good, and the collection contains many Mediterranean forms not to be seen in our northern latitudes. The first floor contains the working-rooms, library, and museum; the upper floor contains the apartments of the Director. In M. Lacaze-Duthier's absence the institution is under the charge of M. Henri Prouho, whose official title is "Préparateur au Laboratoire Arago."

The fauna of Banyuls is probably not nearly so rich as that of Naples, but the advantages to English students would be, the nearer access (twenty-six hours from Paris) and the much more healthy situation.

If I understand rightly, the subvention awarded to the "Laboratoire Arago" by the French Government considerably exceeds that proposed to be given by the Treasury to our new Biological Station at Plymouth. P. L. SCLATER

Port Vendres, Pyrénées Orientales, October 15

KEW GARDENS

THE well-known scientific traveller, Dr. Schweinfurth, has recently paid us a visit in England. The *Berliner Tageblatt* of September 12 reports his impressions of our botanical institutions as given in a lecture delivered the previous day before the "Versammlung deutscher Naturforscher und Aerzte." We extract the account of the National Botanic Garden at Kew. Some trifling

inaccuracies have crept into the report, but we leave them as they stand. The impression produced by English scenery, vegetation, and gardening on unaccustomed eyes is difficult to realise by those to whom they are the common-places of every day.

Dr. Schweinfurth opened his discourse with the remark that England under the influence of a summer sun such as it had enjoyed this year deserved to be called the most beautiful country in the world. Indeed, the ordinarily serious and matter-of-fact man of science seemed to be filled with enthusiasm when relating his observations on botanical institutions in England. He assured them that although he had spent weeks in London he was only in a position to offer them a fragmentary report on the subject. It is true the amiable orator had provided himself with very considerable fragments.

He first of all gave a detailed description of the worldwide renowned Kew Gardens, which he compared to a botanical " Ministry for the Exterior," inasmuch as there the reports of all the embassies and agencies flow together. The development of this gigantic establishment presents similar phases to that of the Berlin Botanic Garden. Originally a kitchen garden for the Royal Court, it has during this century expanded to its present size of about 250 acres. Independently of its varied and enormous botanical treasures, Kew Gardens is one of the most beautiful examples imaginable of park-like arrangement. Everything luxuriates in the most glorious foliage; not a dead leaf nor a dry stalk was to be seen. Everywhere the most untiring and intelligent care was evident; and the manner in which the most delicate plants are brought to their fullest development must excite the universal admiration. The entire administration of this extensive establishment is as simple as it is worthy of imitation.

Kew Gardens contain a vast herbarium which is preserved in a simple light building with open galleries running all round, in which work may be done during the day, but no lights are permitted. Along the walls are placed the cabinets containing the dried plants, which are poisoned with a solution of corrosive sublimate. The arrangement of the species is geographical. A magnificent library and an extensive collection of drawings greatly supplement the usefulness of the herbarium.

The way in which the plants are stuck on sheets of paper throughout their whole surface was deprecated by Dr. Schweinfurth.

Further, Kew Gardens contain seventeen large plant-houses, among which he specially mentioned those devoted to orchids, succulents, and tropical plants, including the palm-house, a building of about the same length as the Berlin palm-house, though by no means so lofty. Of the most beautiful part of the Garden, the colossal rockery of Alpine plants impressed Dr. Schweinfurth most, as it was in its greatest floral richness at the time of his visit.

There are also three spacious museums, situated at some distance from each other, which is a disadvantage; though from the enormous number of visitors—sometimes as many as 80,000 in a day—the separation may have appeared necessary. One of the museums contains a collection of useful vegetable products in various stages of development and manufacture. Another building contains the picture gallery founded by Miss Marianne North, consisting of 800 botanical landscapes from all parts of the world. They mostly represent the general aspects of plants, and their purely scientific value is unequal; but the great care with which the fruit is always painted is worthy of all praise.

LEPIDOPTERA IN THE SIKKIM HIMALAYA

DARJEELING has long been celebrated among entomologists as one of the richest localities in the world for insects, and especially for Lepidoptera, which, owing to the fact of their meeting a ready sale among visitors to the station, are collected as a matter of business by twenty or thirty of the Lepcha and Bhotea inhabitants of Sikkim.

But though many of the superb insects found here are common in collections, little or nothing is known as to their distribution, habits, and time of appearance, as no resident naturalist has ever done much at collecting or observing their habits in person. The number of species is so great, many of them so rare or so uncertain in their appearance, and the difficulty of studying their habits so great, that there is ample room for many years' work in this direction, and the lists which have been published by Mr. De Niceville in several recent numbers of the *Journal of the Asiatic Society of Bengal*, together with the very numerous additions to the known species made by Mr. O. Möller, show what a rich harvest is still to be gathered by one who does not fear exposure to the tropical heat and risk of fever in the low hot valleys where most of them are taken.

Having spent several days recently in observing the butterflies of Sikkim, I may give some idea of their habits and haunts.

First, and by far the most numerous, are the butterflies belonging to the fauna of the Indo-Malay region, which inhabit the low damp valleys from the level of the plains up to about 3500 or 4000 feet. This region is extraordinarily rich in the genus Papilio, of which there are at least thirty species almost confined to it, though some of them on hot sunny days fly far up into higher elevations. Most of these species are many-brooded, and begin to appear in March, continuing till the end of the rains to fly in greater or less numbers. Some of them, however, are only single-brooded; almost all of these appear before the rains, from March to the end of May or June. In the hot valleys they fly at all times of the day up till 4 or 5 p.m., and are only to be procured in quantity and in good condition by those who know their habits, the flowering trees they frequent, the wet spots in the sandy banks of rivers, where they associate in great numbers to settle, and the most attractive baits by which to allure them within reach of the net. This is the sort of work which the Lepcha excels in. He likes the wandering free life in the jungles far better than steady work, and, filling his boxes in two or three days without much exertion by waiting in the favourite haunts of the butterflies, he earns a handsome wage by selling his booty at a pice apiece. He will not trouble himself to catch the small and inconspicuous Lycænidæ and Hesperidæ, unless specially instructed to do so; but, as a fact, these two families are the most numerous in species, if not in individuals, and would probably together amount to at least 200 species in Sikkim, almost all of which, as far as I can learn, are found in this zone of altitude.

Nymphalidæ also are very numerous and very varied, though more difficult to procure. The females of some of them, as well as of some Papilios, remain unknown, or are very rare, notwithstanding the abundance of the males. They do not fly much, or frequent the open sunny places, but remain settled high up on trees, or in dense jungle, where it is impossible to penetrate or to use a net. Many large and splendid moths of the family Agaristidæ are mostly day fliers, and innumerable Bombyces, Geometers, and Sphinges also frequent these hot valleys, and are bred or captured in various ways by the Lepchas, but seldom by Europeans. During the rains, when they are most abundant, the risk of fever at night is too great for much lamp work, and breeding is by the natives but little understood. The smaller moths, especially the Microlepidoptera, remain almost unknown, though some of the most showy sometimes find a place in the boxes of the Lepchas.

When we come to the zone of elevation between 3000 and 6000 feet, we come into a climate which produces the

grandest forest in Sikkim, and surely one of the grandest in the world. A mixture of tropical and temperate forms in highest perfection occurs, oaks, chestnuts, magnolias, laurels, and many other giant trees, laden with climbers, orchids, ferns, aroids, and other epiphytes, till the branches break with their weight, mixed with a number of beautiful shrubs and herbaceous plants. But this forest is almost everywhere, unless strictly protected by the forest department, or growing on slopes too steep for cultivation, destroyed by fire or axe, for the purpose of cropping with rice, millet, Indian corn, and potatoes, which are the principal crops of the natives; and owing to the great extension of cultivation, and the immigration of Nepalese into Sikkim and British Bhotan, a tract of really virgin forest between 3000 and 6000 feet is becoming quite a rarity.

Partly on account of this destruction of the native trees, which are replaced in abandoned cultivation by worthless weeds, such as artemisia, and by quick-growing soft-wooded trees of no value, the species of butterflies peculiar to this zone are much fewer in numbers, both of species and individuals, than lower down, and some of the finer and larger species of Adolea, Limenitis, and Athyona, which formerly were not rare in Sikkim collections, appear to be now very scarce or extinct in their old haunts. A little higher up, however, we find a forest of much the same character, though denser, darker, and the trees much more overgrown with moss. At 7000 and 8000 feet rhododendrons appear, and a dense undergrowth of hill-bamboo, called "maling," which forms the principal fodder for ponies in Darjeeling, in some places makes the forest quite impenetrable. Here the sun shines but rarely during the rainy season, and even in the cold weather mist is very prevalent. This forest is the home of some of the most superb insects in the world.

Let us walk up a few miles above Darjeeling into the great forest which covers Sinchul on a sunny morning early in June, and wait on one of the highest peaks, where a small bare space can be found. Flying over the tops of the trees with a rapid soaring flight we shall see that grand insect *Teinopalpus imperialis*, peculiar to these forests, and if lucky enough to attract him to the ground by a bait, or able to reach his resting-place, we may catch one or two in a morning. But his female so rarely flies from her leafy perch that in sixteen years I only know of three or four examples having been taken, and these one may say by accident in unexpected places. *Papilio Krishna* and *P. Minercus*, again, frequent the same forest; but of the former, though males are in places abundant, the female is hardly, if ever, taken. *Herda duma*, *Picris Horsfieldi*, *Neptes Zaida*, and other species, have the same peculiarity, that the females are hardly ever seen; and only long and patient waiting in spots where sunshine is of rare occurrence, will enable the most sharp-sighted collector to obtain them. Some beautiful, though sombre-coloured, Satyridæ, such as *Lophoessa goalpara*, *Yama*, and others, *Raphicera satricius*, *Lethe scanda*, *Dinarba* and *Sidonis*, are peculiar to these shady, damp forests, and flit along the roads when disturbed in dull weather as well as in sunshine; but however active the search, the number of species and of individuals seen in a day will be small compared to the results of a day in the tropical valleys. Higher up still, from 9000 to 12,000 feet, the outer ranges of Sikkim are very poor in diurnal species, though rich in Geometra, and Micro-Lepidoptera, as the climate is too damp and sunless in summer to encourage the appearance of species of Palæarctic genera, which are in places so abundant on the more sunny, grassy hills of the North-West Himalaya.

In the interior, however, where the climate is drier, and where Coniferæ and rhododendrons form the principal features of the forest from 8000 to 11,000 feet, there are a number of European genera and species which I have at present only procured through native collectors, but which I hope to see for myself before long in life. *Papilio Machaon*, *Colias Fieldii*, *Picris brassica*, *Vanessas*, *Argynnis Lathonia*, the lovely *A. gemmata*, are common in these higher, drier, and more flowery regions, whilst *Parnassius*, *Aneis*, *Melitæa*, and other Alpine genera are also found in certain places. The moths of the interior hills are too little known for me to say much about them, but there are great numbers of species of European aspect, and many novelties amongst them may be expected whenever the Tibetan frontier is crossed.

H. J. ELWES

SKETCH OF THE EARLY HISTORY AND SUBSEQUENT PROGRESS OF PALÆOBOTANY[1]

AMONG the many memoirs included in the Fifth Annual Report of the U.S. Geological Survey, just distributed, none evinces more laborious research than the sketch of palæobotany, and no part of this will prove more valuable, both from its exhaustive treatment and its wealth of references, than the section with the above title. The matter divides itself naturally into a history of the scientific, and of the pre-scientific period. To the latter of course belong the speculations of the early Greek philosophers, whose ideas were far more correct than those held fifteen or sixteen centuries later, for they at least recognised that petrifactions had once been living things, and that the mountains in which sea-shells were embedded had once been under the sea. These doctrines were it appears the popular belief of the Romans, and continued to be held until the spread of Christianity caused them to be rejected, and that long period of stagnation to set in, when all natural science was weighed down and subordinated to the religious cosmogony.

We do not find, however, any direct and unequivocal references to fossil plants or wood in either Greek or Latin writers, though such must have been far from uncommon objects in limestone districts, and the history of palæobotany cannot therefore be said to have commenced before the thirteenth century, when Albertus Magnus described most unmistakably the occurrence of petrified wood.[2] Little further mention, however, is made of any fossil vegetable organism until the latter half of the sixteenth century, when we find several writers describing and discussing the origin of petrified wood, which seems to have added fuel to a controversy that had already for centuries been raging concerning the genesis of petrifactions. Building upon Aristotle's doctrine of spontaneous generation, scholastic writers had come to affirm that it was equally possible for stones to grow of any required form as for living animals and plants. Avicenna in the tenth century had conjured up a *vis lapidifica*, and Albertus Magnus in the thirteenth century had imagined a *virtus formativa*. Bauhin dreamed of some subtle Spirit of the Universe, while Libavius opined that fossils grew, like living things, from germs or seeds. Balthasar Klein obtained a petrified stem, one side being stone, the other coal, an object which excited the liveliest curiosity. He sent the specimen to Matthiolus, who, after studying it, came to the conclusion that coal was a third and final step in the process of transmutation, and that just as wood turned into stone, so stone in turn became transformed into coal. Klein's own views about it seem, however, to have been more rational. The discovery in the mines of Joachimsthal of a petrified trunk with the bark on added to the interest already aroused, and kept alive the discussion.

In 1565, leaf-impressions incrusted in tufa were

[1] From the Fifth Report of the U.S. Geological Survey, by Lester F. Ward, condensed by J. S. Gardner.

[2] For all references the Fifth Report of the U.S. Geological Survey, p. 388 *et seq.*, must be consulted.

described by Kentmann, and in 1664 the existence of leaf-impressions in true rock was for the first time published by Major. In 1699, Lhywd, a Londoner, figured and described a number of ferns from the Coal-Measures, which can even now be recognised. These he was inclined to consider due to the *succus petrificus*, a petrifying juice whose action was controlled by the *vis lapidifica*, both petrifying forces having been invented by Kircher in 1655, when he propounded his theory of *seminaria de corpuscula salina* as the true faith regarding petrifactions. Sperling believed in a special stone-making spirit, and Camerarius (1712) held that in the beginning God had supplied the earth's interior with these varied forms, just as he had placed grass and herbage on its surface. Still others were content to regard fossils as mere freaks of Nature. Such-like ideas held the field, and only began to give way during the early years of the eighteenth century, for we find that, as late as 1733, infinitesimal particles were believed by a Dr. Arnold to have been brought together at the Creation to form dead outlines or images of all the living creatures upon or within the world. During all these dark ages, however, there were not wanting writers who held more rational views as to the nature of fossils, and even combated the supernatural explanations of the dominant schools. It was due to fossil vegetables, according to Brongniart, that these crude ideas came to be abandoned. All these theories were swept away by the "Flood theory," the first germ of which is apparently to be found in Luther's commentary on Genesis, where he expresses the belief that surviving indications of the Deluge would be found in the form of wood hardened into stone around the mines and smelting-mills. Several writers between Luther's time and the close of the sixteenth century held the same view, but the Flood theory was for a time drowned in the more fantastic speculations then in vogue, not to come to the surface again until another century had passed. In 1695 Woodward published a work on fossils, in which he maintained that all the solid parts of the earth's crust were loosened by the Flood and mingled promiscuously in its waters, and that at its close everything sank back to the surface according to its specific gravity, the remains of animals and plants assuming the positions in which they are found petrified. The chiefest expounder of this hypothesis, however, was Scheuchzer, whose great work on fossils, in 1709, laid the foundations of palæobotany, though he subsequently rendered himself even more notorious by describing a large fossil Salamander as *Homo diluvii testis*. His work, however, aroused so deep an interest that for many years collectors and writers were busy searching for and describing fresh evidences in support of the Diluvial theory. It had indeed for some time no serious rival, and remained all but universally accepted down to the second half of the eighteenth century, when dissentients first ventured to make themselves heard. The last two decades of the eighteenth century were destined to witness a collapse of the Diluvial theory as rapid as its rise in the first decade, though Hugh Miller even found supporters of it in our own time.

During the seventeenth century the occasional protests of the rational minority, among whom we find Steno, made few disciples; but during the eighteenth their arguments were felt with increasing force. The Deluge hypothesis, faulty as it was, was a great actual advance, for it at least recognised the real nature of the objects, and turned discussion towards the means through which fossils came to be embedded. Though several authors wrote in a truly scientific spirit during this century, it was Blumenbach who first taught with authority that the beings to whose former existence these fossil forms were due were not only antediluvian, but pre-Adamitic, and that, moreover, there had been a series of faunas and floras inhabiting the earth before the age of man. The change in opinion, however, had long been preparing, and prominent among the questions that led up to it were: Are these the remains of the same kind of plants that are now found growing upon the earth? and, When did the originals live that have been preserved by changing into stone? Only two generations since the answers would have been universally that they were plants that grew but a few thousand years ago, and that they either grew where found, or had been brought from other countries by some such agency as the Flood, or else had been destroyed by these agencies and become extinct. Scheuchzer regarded them as plants which could still be found living, citing a number of genera as examples. Among many others who embraced this view was Lehmann (1756), who laboured hard to prove that the impressions of *Annularia sphenophylloides* were flowers of *Aster montanus*, caught in full bloom, and petrified *in situ*. The exotic theory, as it may be called, first appears in a note of Leibnitz, 1706, on the occurrence of impressions of Indian plants in Germany; and in 1718 Antoine de Jussieu discussed the resemblances of the coal plants of St. Chaumont to ferns of the tropics. Parsons (1757) stated that the Sheppey fruits were absolutely exotic, and Dulac soon after compared the coal plants of St. Etienne to American species. These instances are only a few among many, for similar views became commonly held. Volkmann (1720) and others held what may be described as a degeneration theory, believing that antediluvian vegetation was of a higher order, and free from thorns, thistles, and other scourges, while comprising many fruit-bearing trees of which our modern ones are the degenerate representatives. The same authors held at the same time mixed views, thinking that many of the petrified plants might have become extinct during the Deluge or other physical changes, and it was probably this idea that led to the more critical investigation of the stratified rocks, and brought the question as to when the originals lived within the region of practical science.

THE RECENT EARTHQUAKES AND VOLCANIC ERUPTIONS

TERRIBLE as has been the tale of destruction to life and property during the last six years owing to the exceptional activity of the subterranean forces in nearly every part of the globe, we cannot avoid the reflection that scientific men in the future will feel that there have been at least some compensating advantages for these sad losses. Never before, perhaps, have greater opportunities been afforded to us for collecting the real facts, and for testing, verifying, or correcting hypotheses concerning these interesting phenomena; and never, certainly, have such organised efforts been made to deal adequately with the great opportunities which have been afforded to us.

After the earthquakes at Agram, a Commission appointed by the Hungarian Government was sent to examine the district, and the result was a Report of great value and interest, in which the exact details of the actual phenomena observed were carefully sifted from the mass of vague rumours and gross exaggerations with which they had become involved. Admirable monographs on the terrible earthquakes of Ischia in 1881 and 1883 have been prepared by Prof. Mercalli, of Monza, and by our own countryman, Dr. Johnston-Lavis. The tremendous catastrophe which occurred in the Sunda Straits three years ago has already given rise to a vast mass of literature bearing on the subject. Commissions, including very competent observers, were sent to the district by the Dutch and the French Governments, and the former of these has already completed and published its very valuable Report. We may be certain, too, that the more

recent events, in New Zealand and Charleston respectively, will not be allowed to sink into oblivion until every effort has been made to gather to a focus all the light which they are capable of affording to us on the great problems of vulcanology and seismology.

No one can have studied the reports of the late eruption of Tarawera in New Zealand without being impressed by the energy and enterprise exhibited by the local Press of the colony. The first mail after the outbreak brought us very full and detailed accounts collected by correspondents who, braving no inconsiderable risks, travelled over the scene of the catastrophe to collect information, and these accounts were amply illustrated by maps, sketches, and photographs. It must always be remembered, however, that the requirements of journalism and science are different, and to some extent antagonistic: the former demands, above all things, speed; the latter, accuracy. It is often only when the work of the newspaper correspondent is well-nigh forgotten that the scientific man finds himself in a position to deal with the vass mass of unsifted materials—good, bad, and indifferent—which is poured out before him in such wonderful profusion; to him relations of events can never be "stale" if they are capable of being authenticated and of supplying accurate data for the legitimate inductions of science.

In the case of the Tarawera eruption, as in that of Krakatão, it must be always a subject of regret that the topographical and geological surveys of the scene of the outbreak which were made prior to the event appear to have been far from perfect. Tarawera is situated in the midst of a barren region, in the very heart of the native reserve, and it was moreover most jealously guarded from the intrusions of white men by the superstitious Maoris, who used it as the place for depositing their dead. Dr. Hector, the accomplished Director of the New Zealand Geological Survey, confesses that he had never been able to ascend the Tarawera Range, but that from an examination of its flanks he concluded that it was composed of highly acid (rhyolitic) lavas in *coulées* and dykes, and that large quantities of obsidian and pumice were also present. He was thus led to conclude that Von Hochstetter was right in mapping the mountain as belonging to his recent volcanic series. Mr. Percy Smith, the Assistant Surveyor-General of New Zealand, who like Dr. Hector was upon the spot within a few hours of the outbreak, had been more fortunate in obtaining some knowledge of the upper part of the mountain before the eruption. In the year 1874 he ascended the mountain three times, and found its summit to be destitute of any trace of a crater, but to consist of a table-land about three miles long by half a mile wide, divided into two portions by a saddle, and covered by angular fragments of rhyolite, apparently shivered by the action of frost.

There unfortunately still exists some doubt upon the question as to whether Tarawera has ever been in eruption during the period that New Zealand has been occupied by the Maoris. On the one hand, it has been asserted that no traditions of any previous outbreak are preserved among the natives; but, on the other hand, the names given to the parts of the mountain are said to indicate a knowledge on the part of those who first applied them of its volcanic character, and moreover the extreme sacredness attaching to the locality seems certainly to point to the conclusion that there had been something remarkable in its past history.

Certain it is, however, that, up to June 10 last, Tarawera was not by any means regarded as a spot upon which a volcanic outburst might be expected to break out. But after a series of violent earthquakes occurring on the midnight preceding that day, and lasting for about three-quarters of an hour, a great fissure opened, beginning with an orifice on its northern summit and gradually extending south-westwards to a distance of four miles during the next hour and a half; distinct ejections took place from at least seven vents along this line of fissure. The highly heated condition of the materials thrown from these vents, which set on fire trees at a great distance around the mountain, certainly points to the conclusion that molten lava was ejected from the volcano during this its earliest stage of eruption. But that this lava rapidly became consolidated and no longer incandescent on its surface appears to be clearly established by the observations of Dr. Hector, who, watching the steam cloud on two successive clear nights, was unable to detect any trace of a reflected glow upon it. After the first tremendous outburst, this eruption appears to have been almost entirely a hydrothermal one, and to have slowly but gradually declined in intensity.

Immediately after the completion of the first fissure, there opened a second one throwing out enormous volumes of steam. This second fissure, which eventually attained a length of nearly eight miles, running in a nearly north-and-south direction, was that which passed through the famous lake of Rotomahana. Its ejections seem to have been purely hydrothermal in character, and by the masses of ash and mud thrown out, the beautiful sinter terraces have been apparently converted into mud-volcanoes. There still remains some doubt as to whether the second fissure is not to be regarded as a branch of the first-formed one. The eruptions from a number of vents formed along this second fissure have also been gradually diminishing in intensity; but the quantity of steam and of more or less finely comminuted rock ejected from them has been enormous.

According to the latest accounts which have reached us from the district, the ash, which covers the whole country like a great mantle of snow, effectually prevents the completion of the necessary geological observations upon the scene of the eruption. Indeed, Dr. Hector, after a preliminary survey, felt that no useful detailed work could be done until the rains have removed this covering of loose dust and rendered the country more easily accessible. Mr. Percy Smith has, however, ascended Tarawera, and reports the existence of a great fissure four miles long and five hundred feet wide, of which there seems to have been no trace when he ascended the mountain on former occasions.

It is evident from this brief outline that a number of problems of the greatest interest await solution in connection with the recent display of volcanic energy in New Zealand. Never before, perhaps, have better opportunities been afforded of studying the phenomena attending the formation of the fissures along which volcanic ejections take place. It is remarkable, too, that, although the quantity of materials erupted was very great, there were few if any regular cones of the ordinary pattern built up along the fissures. There also remains much to be learnt concerning the actual nature of the materials ejected at different stages of the outburst, and the way in which they were distributed: all the materials at first thrown out still remain buried under the later ejectamenta.

Upon these and many other problems of the greatest importance we may rely on the geologists of New Zealand, both officials and amateurs, for obtaining all possible evidence during the next few months; and when their researches have been completed the New Zealand eruptions of 1886 can scarcely fail to prove among the most instructive which have ever come under the observation of vulcanologists.

That the terrible catastrophe at Charleston will be similarly utilised by the numerous and able geologists of the United States we cannot for a moment doubt. The telegram despatched by Major Powell during the recent meeting of the British Association at Birmingham shows how fully alive he was to the importance of carrying on systematic observations in the district; among his staff of excellent geologists constituting the United States Geological Survey he will experience no difficulty in

selecting observers admirably qualified for this investigation; nor need we fear that the United States Government will be wanting in their accustomed liberality in publishing the Reports on the subject when they are prepared. Nor will the unofficial geologists of the country and private associations be behindhand in contributing to the mass of information gradually accumulating upon the question of the nature and origin of the terrible event.

ON LION-BREEDING[1]

THE Gardens of the Royal Zoological Society of Ireland have become famous among zoological gardens for their breed of lions. While here and there among the zoological gardens of the world a lion cub is born, none save those of Dublin can boast of a period of lion-cub production of nearly thirty years' duration, or of the extraordinary success of the birth of 131 cubs. This being so, we are indebted to Mr. V. Ball for a history of the subject, which has been published in a recent part of the *Transactions* of the Royal Irish Academy. The subject is one of interest in several ways, and the following short abstract of the details will call our readers' attention to it.

In 1855 a pair of lions from Natal were purchased for these Gardens. The exact relationship of these appears to have been unknown, but their first litter was born in 1857. From 1857 to 1885 we find a total of 131 cubs born, of which twenty-one were either born dead or died shortly after birth, and 110 were reared, eighty-six of these latter being sold, greatly to the profit of the Society and to the advantage of very many of the zoological gardens of Europe, Asia, and America. These 131 cubs were the offspring of nine lionesses and four lions; of the latter, one, "Natal," was the father of forty-two cubs; and another, "Old Charley," who was a son of "Natal's," was the father of forty-six; while of the former, one, "Old Girl," who was born in the Gardens in 1859 as one of a litter of five, was the mother of no less than fifty-five cubs, of which forty-nine were reared. This prolific lioness died at the age of 16 years, apparently of old age.

The facts given by Mr. Ball in one of his very carefully compiled tables seem to indicate two periods of the year at which lionesses in a state of semi-domestication produce their young. While the absence of any well-authenticated information as to the period of the year in which lion cubs are born when in a state of nature is quite remarkable, yet Mr. Ball ventures the fairly safe surmise that considering the period necessary for the rearing and education of a cub to be at the least a year, for the cub is often learning to kill its prey when over a year old, it is most improbable that lionesses have more than one litter in a year when in a wild state; but he thinks it probable that the geographical surroundings of the parents may alter this period, and that it may be in the autumn season in the tropics, when the great heats and droughts of summer are over, and in the spring season in more temperate climes, where the summer warmth would be of service to the young offspring; and he very ingeniously speculates that the two periods of maximum production, as observed in the lionesses in the Dublin Gardens, may have been inherited from two corresponding periods, the result of climatal conditions in a wild state. Another remarkable phenomenon comes to light on comparing the curves of production, when modified into curves of conception, with the monthly curves of temperature for Dublin. In doing so, the maximum curve in the one case is found to closely approximate to the maximum curve of temperature, *i.e.* June and July; and the second maximum curve corresponds to the period of lowest temperature, *i.e.* December and January: but it will be remembered that then the animals are kept in well-heated houses, so that this period, as to temperature, may, though the temperature be artificial, be compared to the other, when it is natural.

The cubs when born are noted as distinctly spotted with dark brown on a ground colour which is rather light brown than fulvous; from about one to three months they are perhaps most distinctly defined; and, though along the back the spots are somewhat quadrangular in shape, there is no indication of actual bars or bands.

In reference to the sexes of the cubs, Mr. Ball is able from accurate information to record the sex of 130 of the cubs, and we find 74 were males and 56 females, giving a majority of 14 males in every 100 cubs. This is an interesting and novel addition to our knowledge of the natural history of the large Carnivores.

No lion or lioness lived in the Gardens for a longer period than 16 years, and it seems probable that 12 to 14 years is the average duration of lion life. The cases so often referred to of lions living to an age of 20 to 30, or the case of "Pompey," who died in the Tower in 1760 at the age of 70, stand on no scientific or even reliable evidence.

Under the heading of "The Cause of Success in Breeding," we find some valuable suggestions as to the keeping of these splendid Carnivores; but we searched in vain for the secret of success. Horse-flesh is evidently not dear in Dublin, as the annual cost of the food of an adult lion, being for the most part horse-flesh, only came to 15*l.* in 1885. A series of tables accompanies the memoir, and some illustrations of the cubs of the lioness "Queen," born April 1885, from drawings by Mr. Thomas.

[1] "Observations on Lion-Breeding in the Gardens of the Royal Zoological Society of Ireland," by V. Ball, M.A., F.R.S., Director of the Science and Art Museum, Dublin, and Hon. Sec. of the Royal Zoological Society of Ireland. *Transactions* of the Royal Irish Academy, vol. xxviii. Part 24, August 1886.

NOTES

AN article in NATURE for May 6 (p. 7) drew attention to the fact that this present year is the tercentenary of the introduction of the potato into England, and discussed some of the points of its history. Apart from the purely historic aspects of the question, "Whence did our potato first come?" it was shown that in connection with the suggestion of cross-breeding to strengthen against disease it is very important to know which is the species that for three hundred years we have been cultivating. With a view to drawing the attention of cultivators to the subject, it is proposed to hold a Tercentenary Potato Exhibition at the St. Stephen's Hall, Westminster, from Wednesday, December 1, to Saturday, December 4, and to appoint one of those days for a Conference, when some of the unsettled questions may be discussed. The Exhibition will consist of four sections:—(1) An historic and scientific collection, to include early works on botany, in which the potato is figured; maps showing the European knowledge of the New World three hundred year ago, and the proximity of potato-growing districts to the ports most frequented; early books on travel and voyages in which references to the potato occur; works and papers in which attempts to define the different species are made; illustrations of the species and varieties; contemporary references to the voyages of Hawkins, Drake, Grenville, and Raleigh. (2) Illustrations of potato disease, and works on the subject. (Sections 1 and 2 will be arranged under the advice of a committee of scientific gentlemen who have consented to give their co-operation.) (3) Methods for storing, preserving, and using partly diseased potatoes, &c. (4) A display of tubers of all the various varieties grown. (In this section gold, silver, and bronze medals will be awarded. Each exhibit must be accompanied by a statement of date of planting, locality, nature of soil, &c.)

Mr. John Whitehead, well known to ornithologists for his discovery of a new species of Nuthatch in Corsica, has been travelling in Borneo during the last two years, and has sent home a large collection of birds. Unfortunately the disturbed state of the country in the Brunei district has prevented Mr. Whitehead from accomplishing the chief object of his expedition, the ascent of Kina Balu, and he has therefore been obliged to restrict his labours to the neighbourhood of Labuan and the country round Sandakan. These districts have been well worked for years by Mr. Alfred Everett, Mr. Treacher, Mr. Pryer, and other naturalists, and Mr. Whitehead's collection, although very complete, did not contain anything new to science. He is now travelling in Java, and purposes to explore some of the mountain-ranges in the interior.

Mr. George Reid, a well-known contributor to the pages of Mr. Allan Hume's journal, *Stray Feathers*, has just finished a "Catalogue of the Birds in the Provincial Museum, N.W.P. and Oudh, Lucknow." Mr. Reid is the member of the Committee of Management in charge of the Natural History Department of the Lucknow Museum, and the value of the bird-collection depends upon the series which Mr. Reid has himself given to the Museum, his donation amounting to 1287 specimens out of a total of 2646. The Museum appears to possess a very complete collection of birds from the neighbourhood of Lucknow, and it is encouraging to see that Mr. Reid, in re-organising the natural history portion of the Museum under his charge, has recognised the first duties of a local institution, and has commenced by making a good collection of the birds of the province, of which Lucknow is the capital. Mr. Reid will be glad to entertain the idea of exchanges with other Museums.

The concluding part of the late John Gould's "Supplement" to his "Monograph of the Trochilidæ" will shortly be issued by Messrs. Sotheran. This work, which was left unfinished at Mr. Gould's death, has been completed by Mr. Bowdler Sharpe, who has also nearly finished the great work on the "Birds of New Guinea," which had not long been commenced by the author before he died.

Messrs. Taylor and Francis will shortly publish a work by Mr. T. Mellard Reade, F.G.S., entitled "The Origin of Mountain-Ranges." In addition to containing a systematic theory of mountain-building, with detailed experimental illustrations, the structure and geological history of the great mountain-masses of the globe will be discussed. The work will also contain many maps and sections of mountain-ranges, and a contoured map of the North Atlantic Ocean, together with numerous sketches of mountain-structure and scenery, from Nature, by the author.

Prof. R. H. Richards, of Springfield, Massachusetts, has invented an ingenious and effective application of the zoëtrope for the illustration of the relation between certain isomeric forms. The apparatus exhibits the gradual passing of a cube into an octahedron, a dodecahedron, &c. It can be used also for exhibiting the growth of hemihedral forms of crystals.

A project is on foot for tunnelling the "Great Divide." The Divide is the Rocky Mountains, and the point proposed to be tunnelled is under Gray's Peak, which rises no less than 14,441 feet above the level of the sea. At 4441 feet below the peak, by tunnelling from east to west for 25,000 feet direct, communication would be opened between the valleys on the Atlantic slope and those of the Pacific side. This would shorten the distance between Denver, in Colorado, and Salt Lake City, in Utah, and consequently the distance between the Missouri River, say at St. Louis, and San Francisco, nearly 300 miles; and there would be little more required in the way of ascending or descending or tunnelling mountains. Part of the work has already been accomplished. The country from the Missouri to the foot of the Rockies rises gradually in rolling prairie till an elevation is reached of 5200 feet above the sea-level. The Rockies themselves rise at various places to a height exceeding 11,000 feet. Of the twenty most famous passes, only seven are below 10,000 feet, while five are upwards of 12,000 feet, and one, the Argentine, is 13,000 feet. Of the seventy-three important towns in Colorado, only twelve are below 5000 feet, ten are over 10,000 feet, and one is 14,000. The point from which it is proposed to tunnel is 60 miles due west from Denver, and although one of the highest peaks, it is by far the narrowest in the great backbone of the American continent.

At a meeting on Tuesday of the Committee of the subscribers to the British School of Archæology at Athens, Prof. Jebb said the School had been erected and paid for, Mr. F. C. Penrose had been appointed Director, and a provisional income of 400*l.* a year for three years had been raised; but additional funds were required. Prof. C. T. Newton, in urging the importance of having a great School of Archæology, suggested that there should ultimately be raised a special fund for the payment of the travelling expenses of the students at Athens. On the motion of Prof. Jebb, a Managing Committee was appointed.

On Saturday last, after six in the evening, several shocks of earthquake were felt in Alsace and many other parts in the nearest Alpine valleys, in the Vosges, and in the Black Forest. At Strasburg there had not been any earthquake for almost 200 years. The direction of the movement was from north to south. Several of the shocks were rather severe.

A telegram from Halifax, October 14, states that a shock of earthquake lasting ten seconds had been felt at Sydney, Cape Breton Island, Canada.

The Rev. J. H. Abrahall writes from Combe Vicarage, Woodstock, that on September 30, while near Blenheim Park, walking westwards about 7 p.m., he was aware of a sudden splendour above him on his left. Turning towards it, he saw a meteor moving eastward. It pursued a level path beneath the Milky Way about a sixth of the distance from the zenith to the horizon. It was bigger than Jupiter, and of a yellow hue. A reddish flame curled, crest-like, backward from its top. Its course was slow, and it quenched the light of the stars it passed over. It soon vanished, leaving no luminous train.

We have already referred to two successive instalments of Mr. Taylor's papers on the aborigines of Formosa, which have appeared in the *China Review* of Hong Kong. The third and last is now before us. It first describes the Pepo-huans, who are really not aborigines at all, but who stand between the savages and the Chinese settlers, speaking the language of both. They are believed by themselves and the other tribes to be the result of mixed marriages between whites and Chinese, who have traded to the country or been wrecked on the coasts, and aboriginal women. They are a simple, harmless, peaceful people. The Diaramocks, who inhabit the mountain-ranges which form the north-western boundary of the Tipuns (already described), are a fierce and intractable race, addicted to cannibalism. Little is known about them, as they hold aloof from other tribes. They are supposed to be the true aboriginal inhabitants of Formosa. There is also said to be a tribe of red-haired savages, living amongst the central mountains, but no authentic information has been gained respecting them. The inhabitants of Formosa generally are described as inquisitive and intelligent. The Chinese have a proverb to the effect that when the savages take to wearing trousers there is no opening

left for a Chinaman. The custom of head-hunting which prevails in some districts is mainly intended to prove the valour of the young men. On the whole, Mr. Taylor has given us a large number of details, classified under various tribes, which were not known before.

IN the September number of the *Meteorologische Zeitschrift*, Prof. Hann gives the results of many years' observations on the temperatures of the various parts of the Vienna forest. The forest valleys have a considerably lower temperature than the open land outside. This difference is smallest in winter and greatest in summer. But there is no similar effect during the course of the day, for the afternoon difference is not the greatest. It is actually least in the warmer hours of the day, and greatest in the cooler part. In the early morning and evening the influence of the forest in lowering the temperature of the air is greatest.

THE last number (vol. lv. Part 2, No. 2, 1886) of the *Journal* of the Asiatic Society of Bengal has for its first paper a list of butterflies taken in Kumaon, a district in the middle portion of the Himalayas, lying between Garhwal and Nepaul, by Mr. Doherty, of Cincinnati, who spent several months towards the close of last year in the expedition. Mr. Doherty's failure in the higher regions bordering on Tibet leads him to advise entomologists that the three summer months are the only good ones for collecting, either on the desert plains of Tibet, or in the deep valleys of the Himalayas sheltered by the outer range from the violence of the monsoon rains. Dr. Barclay contributes two papers—one on a second species of Uredine affecting the Himalayan spruce-fir (*Abies Smithiana*, Forbes), the first being described in the first paper of the present volume; the second paper by the same writer relates also to new species of Uredine parasitic in the deodar (*Cedrus deodara*, Loudon). Mr. Atkinson concludes his six papers on the Indian *Rhynchota*, which have been compiled in order "to provide those who may become interested in this order of insects with some guide to their classification and arrangement, and was at first devoted to the correction of our only English list, but this became so unsatisfactory that it was found better to revise the whole on the basis of Stål's numerous and elaborate essays." The number of species described under each family is: *Cicadidæ*, 115; *Cercopidæ*, 67; *Membracidæ*, 33; *Jassidæ*, 38; *Fulgoridæ*, 204. These figures, Mr. Atkinson adds, could probably be doubled in a few years, for the number of *Jassidæ* alone awaiting examination should add several hundred species to the Indian fauna. Dr. King adds three apparently new Primulas from the higher parts of the Eastern Himalayas to the *Primulaceæ* of Sir Joseph Hooker in his "Flora of British India." Finally M. de Nicéville has a paper "On the Life-History of Certain Calcutta Species of *Satyrinæ*, with special reference to the Seasonal Dimorphism alleged to occur in them."

ANOTHER consignment of German carp (*Cyprinus carpio*) is to be imported by the National Fish Culture Association to meet the growing demand for this species, which is superior to its congener of this country. The Association, through its secretary, Mr. Oldham Chambers, has urged upon those possessing disused waters to introduce the carp, both the mirror and leather species, therein. Although the German carp belongs to the same genus as the English, the former is being imported to improve the latter, which have deteriorated in flavour and condition owing to lack of cultivation. The fish will be committed to the charge of the Marquess of Exeter's pisciculturist, who has proceeded to Germany for the purpose of bringing them over, together with other species.

AN amusing incident occurred last week at the Colonial and Indian Exhibition Aquarium, where a remarkable raven from the Isle of Mull is now on view. On being fed it is the habit of this bird to hide the remnants of its repast in various parts of its habitat, and exhume them when prompted by hunger to renew the meal. One day a rat invaded the spot, and commenced to excavate for the hidden articles of consumption. Enraged at this proceeding, the raven fell upon the rodent, and gored it to death after a severe struggle on both sides.

MESSRS. WHITTAKER AND CO. will issue in the course of next week "On the Conversion of Heat into Work, a practical Hand-book on Heat Engines," by Mr. Wm. Anderson, M.I.C.E.

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus* ♂) from India, presented by Mr. T. L. Brewer; a Macaque Monkey (*Macacus cynomolgus* ♂) from India, presented by Mr. Walter C. Horsley; a Bonnet Monkey (*Macacus sinicus* ♂) from India, presented by Mrs. Samuel Lloyd; a Common Squirrel (*Sciurus vulgaris*), British, presented by Miss F. Westrup; two Grey Seals (*Halichœrus grypus*) from the Island of Canna, N.B., presented by Mr. R. Thom; a Varying Hare (*Lepus variabilis*) from Perthshire, presented by Mr. T. West Carnie; a Goshawk (*Astur palumbarius*) from France, presented by the Baron D'Epremesnil; a Golden Plover (*Charadrius pluvialis*), British, presented by Mr. G. Smith; ten Common Vipers (*Vipera berus*), British, presented by Mr. C. F. McNiven; two Black-footed Penguins (*Spheniscus demersus*) from South Africa, purchased.

OUR ASTRONOMICAL COLUMN

THE BINARY STAR τ CYGNI.—Mr. J. E. Gore (who has taken up this branch of astronomy with great vigour) has published in the *Astronomische Nachrichten*, No. 2749, elements of the orbit of τ Cygni. Using the measures of Dembowski, Burnham, Frisby, and Tarrant, he finds:—

$P = 53{\cdot}87$ years	$\Omega = 83^\circ\ 0'$
$T = 1863{\cdot}99$	$\lambda = 205^\circ\ 26'$
$e = 0{\cdot}3475$	$a = 1''{\cdot}19$
$\gamma = 44^\circ\ 40'$	$\mu = -\ 6^\circ{\cdot}68.$

These elements represent the observations fairly well. It must be remembered, however, that the measures only extend over a period of ten years, and the orbit must therefore be considered, as Mr. Gore states, to be provisional only.

THE LICK OBSERVATORY.—We learn from *Science*, vol. viii. No. 190, that the following plan has been devised by Prof. Holden for the working of the great telescope:—"We mean to put the large telescope at the disposition of the world by inviting its most distinguished astronomers to visit us one at a time, and to give to them the use of the instrument during specific hours of the twenty-four. Each day there will be certain hours set apart when the Observatory staff will relinquish the use of the equatorial to distinguished specialists who will come from the United States and from Europe to solve or to attack some one of the many unsolved problems of astronomy. In this way we hope to make the gift of Mr. Lick one which is truly a gift to science, and not merely a gift to California and to its University."

COMET BARNARD (1886 *f*).—Dr. J. von Hepperger has published the following elements and ephemeris for the comet discovered by Mr. Barnard on October 4:—

$$T = 1886 \text{ December } 24{\cdot}3064 \text{ Berlin M.T.}$$

$$\left.\begin{aligned} \pi - \Omega &= 78^\circ\ 56'\ 20'' \\ \Omega &= 140\ 17\ 55 \\ i &= 93\ 33\ 52 \end{aligned}\right\} \text{Mean Eq. } 1886{\cdot}0.$$

$$\log q = 9{\cdot}91236$$

Error of middle place ($O - C$).

$$d\lambda \cos\beta = -\ 8 \qquad d\beta = -\ 1.$$

Ephemeris for Berlin Midnight

1886	R.A. h. m. s.	Decl. ° ′	Log Δ	Log *r*	Brightness
Oct. 22	11 16 13	3 57·6 N.	0·2961	0·1434	1·86
26	11 27 15	4 21·1	0·2747	0·1296	2·21
30	11 39 16	5 53·2	0·2520	0·1093	2·66
Nov. 3	11 52 28	7 1·7 N.	0·2281	0·0916	3·22

The brightness on October 6 is taken as unity.

10 SAGITTÆ.—Mr. S. C. Chandler has discussed, in the *Astronomische Nachrichten*, Mr. Gore's observations of this star, together with some of his own, and some observations made for the Harvard and Oxford Photometric Catalogues. The result of his inquiry is to give M = 1885 December 4d. 9h. 36m. G.M.T. + 8d. 9h. 11·0m. (E – 391), the duration of increase being 3·00d., and of decrease 5·38d., and the magnitude at maximum being 5·6, and at minimum 6·4. Mr. Chandler considers it likely that the period will prove to be within two minutes of the truth. Mr. Espin's value, however, is 1h. 28m. shorter.

THE OBSERVATORY OF RIO DE JANEIRO.—M. Cruls, in a communication to the Paris Academy of Sciences, states that the long-talked-of transference of the Rio Observatory is about to be commenced. The site chosen lies nearly on the same parallel as the present Observatory, but two minutes farther to the west. The Brazilian Observatory possesses, from its proximity to the tropic, an advantage over all others, in that for forty days in the year the sun's zenith distance does not exceed 1°. M. Cruls anticipates that in the new edifice he will be able to undertake, with success, observations of terrestrial magnetism, and of atmospheric electricity, and he would wish to set up a delicate seismograph for recording slight movements of the soil. He trusts also that the Observatory will bear its share in the great photographic survey of the heavens proposed by Admiral Mouchez.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1886 *OCTOBER* 24–30

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on October 24

Sun rises, 6h. 41m.; souths, 11h. 44m. 16·6s.; sets, 16h. 47m.; decl. on meridian, 11° 50′ S.: Sidereal Time at Sunset, 18h. 59m.

Moon (New on October 27) rises, 2h. 37m.; souths, 9h. 19m.; sets, 15h. 48m.; decl. on meridian, 4° 45′ N.

Planet	Rises h. m.	Souths h. m.	Sets h. m.	Decl. on meridian ° ′
Mercury	8 22	12 47	17 12	18 30 S.
Venus	5 41	11 9	16 37	6 58 S.
Mars	10 44	14 37	18 30	23 30 S.
Jupiter	5 33	11 3	16 33	6 37 S.
Saturn	21 24*	5 26	13 28	21 18 N.

* Indicates that the rising is that of the preceding evening.

Oct.	h.	
30	10	Mars in conjunction with and 6° 5′ south of the Moon.

Variable Stars

Star	R.A. h. m.	Decl. ° ′		h. m.	
U Cephei	0 52·2	81 16 N.	Oct. 24,	4 51	*m*
			,, 28,	4 30	*m*

			,, 29,	21 22	*m*
U Ophiuchi	17 10·8	1 20 N.	,, 24,	1 19	*m*
			and at intervals of	20 8	
β Lyræ	18 45·9	33 14 N.	Oct. 30,	21 30	*m*
S Vulpeculæ	19 43·7	27 0 N.	,, 28,		*M*
R Sagittæ	20 8·9	16 23 N.	,, 29,		*m*
δ Cephei	22 24·9	57 50 N.	,, 25,	2 30	*M*
			,, 28,	21 30	*m*

M signifies maximum; *m* minimum.

Meteor Showers

The present week offers fewer active radiants than the one just past. The following radiants are, however, represented:—Near β Canis Minoris, R.A. 105°, Decl. 12° N.; and from Cancer, R A. 133°, Decl. 21° N. Both yield swift meteors, especially the latter. October 24 and 29 are fireball dates.

GEOGRAPHICAL NOTES

THE last volume of the *Izvestia* of the Caucasus Geographical Society (vol. viii. 2) contains a great variety of geographical information. General Stebnitzky contributes a most interesting paper on the figure of the earth, being a discussion of results obtained from pendulum-observations in connection with the opinions expressed by M. Faye. An excellent map of the province of Kubañ, on a scale of 13 miles to an inch, is accompanied by a sketch of the colonisation of the province, which already has a Russian population of more than one million inhabitants. M. Koshkul gives a short description of the "Naphtha Mountain," in the Transcaspian region. The telegraphic determination of the longitudes of Tiflis, Shemakha, and Baku acquires the more interest, as it allows of the determination of the general error (14″·3) of the Caucasian triangulation and the deviations from the vertical line, due to local causes at these three places. A list of points whose positition has been determined by the triangulation made in the Transcaspian region, as also in Khiva and Bukhara, is given by MM. Pervas and Gedeonoff, and will be most welcome to cartographers. Among the notes we notice the following:—On the Caucasians of Kubañ, due to M. Zagursky, whose researches on the languages of the Caucasus are always so great a help to ethnography; a list of the Caucasian population in Kubañ in 1883, from which we learn that from Kubañ alone no less than 13,600 Circassians have emigrated since 1871; M. Chantre's craniological measurements are summed up by M. Zagursky; and M. Lessar contributes a paper on the north-western frontier of Afghanistan. The "Appendix" shows where the chief attention of the Caucasus Geographical Society is now directed. They contain translations of a work dealing with Armenia (the "Toros Akhpar" guide through Armenia, by the Archbishop Garegin Srvandzyantz); of the Turkish "Salname" for the Erzeroum Vilayet; of notes on Syrian-Khaldeans, by a native from Hosrabad; and of Mr. Charles Wilson's lecture on Asia Minor, delivered before the London Geographical Society.

THE first fascicule of the full Reports of the Polar Meteorological Station at the mouth of the Lena has just been published. It is the first fascicule of the second part, and contains the meteorological observations made since September 1, 1882, to August 31, 1883, compiled by M. Eigner, and published under the supervision of Dr. R. Lenz; the second fascicule of the same volume will contain the meteorological observations in 1883–84; while the first volume is reserved to magnetical observations, and the third will be devoted to the non-obligatory observations, among which the auroræ will occupy a prominent place. The meteorological observations now published, comprise the pressure of air, the temperature, elasticity of vapours, relative moistness, force and duration of wind, nebulosity, snow and rain, as also the temperature on the surface of the soil and the snow, and at depths of 40, 80, and 160 cm., these last two missing for the months of July and August 1883, in consequence of an accident to a thermometer. All observations are given in full, that is, for every hour, as also the monthly averages. The daily range of all elements is also represented by curves, whose scale is exactly that accepted for the publication of the French observations at Cape Horn; the work is accompanied, moreover, by a map of the mouth of the Lena, and of the station itself, as also by a drawing representing the station amidst the tundra, on the banks of a branch of the Lena. A full description of the instruments and their corrections is given both in Russian and in German.

THE October number of the *Proceedings* of the Royal Geographical Society has for its leading paper one by Sir Francis de Winton, on the Congo Free State, the conditions of its administration by Europeans, and its probable future. In this latter respect Sir Francis de Winton is naturally inclined to look on the favourable side. Of more strictly geographical interest is the letter from Mr. Grenfell recounting his latest explorations in the missionary steamer *Peace*, of the tributaries of the Congo, between Leopoldville and Stanley Falls, with very detailed maps.

Petermann's Mitteilungen for October contains a long paper by M. Nikitin, the chief geologist of the Russian Geological Committee on Glaciers in Russia. His object is to lay down the limits of the traces of glacial action in that country. Lieut. von François's journeys in the southern Congo basin are the subject of the next paper; and, finally, there is a brief account

of the Cunos or Tulé Indians of Darien, from the reports of a missionary sent to labour among them to Bishop Thiel, of Costa Rica, who has communicated them to Herr Polakowsky.

THE current *Mittheilungen* (Band xxix. Nos. 7 and 8) of the Geographical Society of Vienna contains letters from Dr. Lenz and Herr Baumann, from the Congo, and part of an account by Dr. Holub of his present journeyings in South Africa. Of special interest are two papers on the Hauslab cartographical collection. One describes the general extent and contents of the collection, which is in three parts: (1) books; (2) engravings; (3) maps. The last contains about 4500 sheets, and is especially rich in old specimens of cartography. Two of these form the subject of a second paper: they are a globe, the author of which is unknown, but which probably dates from soon after Columbus; the other is a chart of the Mediterranean dated 1513.

THE FIFTY-NINTH MEETING OF GERMAN NATURALISTS AND PHYSICIANS, BERLIN, SEPTEMBER 18–27

[FROM OUR BERLIN CORRESPONDENT]

THE present has in every respect been the most important of these annual meetings. Even in the number of visitors it far exceeds any similar reunion since the foundation of the Society, as many as 2224 members, and 1931 associates, or 4155 altogether, having entered their names, while no less than 1496 ladies took part in the general proceedings and social gatherings. It may here be remarked that the constitution of the German Naturalists' Society differs essentially from that of the British Association, as it exists only so long as the meeting lasts, and consists of members—that is, of persons who have published treatises, other than dissertations for academical honours, on general scientific and medical subjects—and of ordinary associates. Two or three sittings are devoted to the formal proceedings, such especially as the choice of the following year's place of meeting, and of the two leaders, whose duty it is to summon the next assembly, and arrange the work on hand. The general sittings are occupied with matter of universal interest, and are attended in common by all members, associates, and ladies. The more strictly scientific work, however, is distributed amongst the several Sections, thirty on this occasion, each of which is presided over by a freshly elected chairman, and set apart for the discussion of papers by specialists. After the last general sitting, at which the annual meeting is officially dissolved, it ceases for the time being to exist. Enjoying no special source of income, and keeping no permanent records, it possesses in the officers appointed to arrange for the next gathering the only germ of a new and equally ephemeral existence. To this temporary organisation corresponds the manner in which its proceedings are issued. An official journal, published only while the gatherings are held, contains the proceedings of the general sittings *in extenso*, those of the various Sections in shorter or more detailed reports. It may here be mentioned that, at the suggestion of the administration, a Commission was on this occasion appointed for the purpose of reporting to next year's meeting any proposals for a modification of the statutes. Reference was made more especially to such a change as would confer on the German Naturalists' Society a more stable existence; in fact, an organisation somewhat similar to that of the British Association.

Of the 4155 members and associates present, Berlin was represented by 1444, other places by 2711 (including 429 foreigners), as under: Europe, 347; America, 54; Asia, 18; Africa, 6; Australia, 4. Most of the leading representatives of German science were present, although illness unfortunately prevented the attendance of Von Helmholtz, Kirchoff, and Wislicenus, the first and last of whom had undertaken to deal with some matters of general interest.

Under the presidency of the two administrators, Prof. Rudolf Virchow and Prof. A. W. Hofmann, the first sitting was held on Saturday, September 18, when an audience filling the spacious Circus Renz was addressed by Herr Virchow on the development of the Society from modest beginnings, and its present importance for the mutual interdependence of the various branches of the natural and therapeutic sciences. He dwelt on the progress made since the first meeting in Berlin, in 1828, under the presidency of Alexander von Humboldt, which had been attended by Oerstedt, Berzelius, Gauss, Weber, Johannes Müller, Mitscherlich, Rose, Magnus, Ehrenberg, but from which Goethe had absented himself. The importance of these illustrious *savants* for the development of the physico-chemical and biological sciences, and the continuity of their researches with the problems now under discussion, formed the conclusion of this highly instructive opening address. After receiving the felicitations of the representative of the Minister of Public Instruction, Von Gossler, of the Berlin Oberbürgermeister, and the Rector of the University, and after the meeting had made choice of Wiesbaden for next year's gathering under Prof. Fresenius and Dr. Pagenstecher, Dr. Werner Siemens discoursed on "The Scientific Character of the Age." The speaker dilated on the spread of the natural sciences through these periodical gatherings and through their introduction into the school-room, thus influencing the *technique* of the arts, which in their turn react powerfully on the social relations, so that, by his command of the forces of Nature, man is now enabled to produre the necessaries and the pleasures of life in greater abundance with less expenditure of time and labour. He is certainly not able to overcome all the evils inherent to the present period of transition; but our scientific age promises to discover all the remedies calculated to alleviate and cure the ills from which we now suffer.

At the second general sitting, held on September 22, Prof. Pohlmann, of Buffalo, conveyed the greetings of the American Association to the German Naturalists, together with a general invitation to the International Medical Congress to be held next year in Washington. Prof. Ferdinand Cohn, of Breslau, then spoke on "Vital Questions," dealing with the nature of life from the present scientific stand-point, in reference more especially to the simplest living beings, the lowest plants, whose vital functions he described in attractive language. He considered that we had already half solved the riddle of life, inasmuch as we had grasped its mechanism and the physical and chemical forces which set it in motion. But we have to face other phenomena and active forces, which must be clearly fathomed by the more fortunate efforts of future research, so that the full solution of the problem of life may perhaps be deferred to a remote period. The next speaker was Herr George Schweinfurth, from Cairo, who spoke on "Europe's Mission and Prospects in Central Africa," arguing energetically for the possibility and necessity of colonising that region. He described the wealth of this continent, both in natural resources and available labour, which by colonisation alone could be properly utilised in order not only to insure a happy and worthy future for the natives of Africa, but also to open a wide field of fruitful activity for the already crowded populations of Europe. He warmly combated the assumptions that its tropical climate closed the door of Africa to most Europeans, and that acclimatisation was impossible. Under certain precautionary measures, and when Western culture has reclaimed Africa by railways, draining, disafforestation, tillage, and stock-breeding, just as Europe itself has been reclaimed by the hand of man, then the white race will find itself as much at home in Africa as the Negro. After the transaction of some formal business, Prof. His, of Leipzig, addressed the meeting on "The Development of the Zoological Station at Naples, and on the Growing Urgency of a Scientific Central Establishment." From the information gained by repeated personal visits, he gave a vivid description of the Neapolitan Station, and concluded by indicating the chief objects of such a central institution as he considered should now be founded. Amongst these objects he mentioned the investigation of the anatomy of the brain, which could be best carried out in such a central station.

At the third general sitting, held on September 24, Dr. Ludwig Wolf, of Dresden, reported on his journey to Central Africa, describing his route from Leopoldville, on the Kassai, and its copious affluent, the Sankuru, through the domain of the Bakutu, the Bakuba, the Balula, and Lunda peoples. He gave an animated picture of his experiences on this journey, which he made as a member of the Wissmann Expedition. He was followed by Prof. Neumayer, of Hamburg, who urged the necessity of Antarctic exploration, dilating especially on its importance for geology and palæontology. From it he anticipated an answer to the question how, as he assumed, the South Pole had been a centre of dispersion for living organisms throughout the southern, as the North Pole is now generally supposed to have been for the northern hemisphere. He further dwelt upon the great value of terrestrial magnetic observations in high southern latitudes, since in the far north a whole chain of stations had recorded the extent of the fluctuations of the magnetic needle. Simultaneous observations in the north and south will alone enable us to arrive at definite conclusions on the nature of

terrestrial magnetism and its relations to the earth-currents, Polar lights, and solar energy. Prof. Bergmann, of Berlin, followed with some remarks on the relations of modern surgery to the treatment of internal ailments. After some formal proceedings, the third general sitting, and with it the fifty-ninth gathering of the German Naturalists and Physicians, were brought to a close.

In a brief report of this nature it would be impossible to do more than refer in the most summary way to the work done in the several Sections, of which twelve were devoted to scientific and eighteen to medical subjects. Altogether 522 topics were discussed, and 155 demonstrations carried out. Most of the proceedings will be published in special scientific journals, and here it will suffice to mention more especially the remarkable synthesis of coniine, the poisonous alkaloid of hemlock, effected with surprising success by Prof. Ladenburg. Thanks to this achievement, the artificial production of a vegetable alkaloid may now for the first time be regarded as successfully accomplished. In the physiological department the question of the localisation of the cerebral functions gave rise to an animated discussion, in which Profs. Hitzig, Munth, and Soltz took part. In the section devoted to the subject of scientific instruction, Prof. Haeckel pleaded strongly for a severer training in this branch of knowledge amongst young students. It may be mentioned in conclusion that, in connection with this meeting, an exhibition of scientific instruments, apparatus, and educational appliances was held in the apartments of the Academy of Arts and Sciences. There was a good show of instruments of precision, microscopes, electric, medical, and other appliances, which attracted a large number of visitors during the few days the exhibition lasted, from September 16 to 26.

THE HARVEIAN ORATION

DR. PAVY, F.R.S., delivered the Harveian Oration at the Royal College of Physicians on Monday afternoon. After giving the directions marked out by the founder of the Oration—viz., to commemorate the benefactions that have fallen into the possession of the College and to search and study out the secrets of Nature by way of experiment—the orator alluded to the augmentation which the income from the endowment of the Croomian Lectureship has recently undergone, by which the amount available is raised from 10*l.* to 200*l.* per annum; and to the sum (2000*l.*) bequeathed by the late Dr. Gavin Milroy. He next spoke of the course pursued by Harvey as set forth by Lord Bacon, in his "Novum Organum," or "true directions concerning the interpretation of Nature." Instead of giving himself up, as others had done before him, to arguing out conclusions from accepted axioms, Harvey struck out, Dr. Pavy continued, into the hitherto untrodden path of inquiry—that of induction—and sought knowledge by a direct appeal to Nature through the medium of observation and experiment. "It were disgraceful," he says, "with this most spacious and admirable realm of Nature before us, did we take the reports of others upon trust, and go on coining crude problems out of these, and on them hanging knotty and captious and petty disputations. Nature is herself to be addressed, the paths she shows us are to be boldly trodden." In the discovery of the circulation Harvey applied the principles of induction and argued upon them in a strictly logical way. He showed himself to be a good and careful observer, judged even by the standard set forth by John Stuart Mill on the process of observing. The experiments which Harvey conducted on the arteries and veins, to assist him in his inquiry, were founded upon a well-devised plan. Dr. Pavy next spoke of the new departure in physiology which Harvey's discovery established, of the opposition with which his views were received, and remarked that the high position in his profession he had attained did not suffice to secure his escape from the effect of the prejudice against innovation entertained by the multitude. Aubrey tells us he had "heard him say that after his book on the circulation of the blood came out he fell mightily in his practice; 'twas believed by the vulgar that he was crack-brained, and all the physitians were against him." Harvey lived, however, to see his doctrine generally accepted. The orator next referred to one issue of research derived, he said, from the labours of the present day, which has already yielded much good and useful fruit and gives promise of yielding much more. "Belonging to the realm of living Nature there are," he continued, "small organisms, the existence of which we must have remained unconscious of in the absence of the aid of the microscope. These bodies are known by the name of bacteria or bacilli, and, while some difference of opinion has existed, it is generally thought that they are organisms belonging to the vegetable kingdom. There is nothing in their appearance to strike the observer that they possess any significance, and yet by recent research it has been found that they play a most important part as constituents of the living world." The experiments of Spallanzani, Schulze, and Swann, were next described by Dr. Pavy, the natural conclusion to be drawn from which, he said, "goes far towards absolutely establishing that the air contains the germs of living organisms, and that it is these that constitute the source of the microscopic organisms found to become developed in the presence of organic matter, which some have contended take rise spontaneously. This view is supported by the researches of the present day, and nothing that would bear the scrutiny of strict investigation has ever been adduced against it. It stands at the foundation of our modern notions regarding the *rôle* played by bacilli, and thus occupies a position of weighty importance with reference to the matter. The step from the action exerted by bacteria as agents exciting the decomposition of organic products to that which brings them before us as a source of disease is not a large one. In the one case they lead to change which would not otherwise occur, and in the other they disturb the order of changes naturally taking place and thus induce an abnormal state; and although there is nothing in their morphological characters to show the reason, different trains of phenomena—in other words, different diseases—are occasioned by different kinds of bacilli. . . . Through the indefatigable researches of Pasteur and others the distinguishing form and life-history of certain of these organisms have been clearly made out. Placed under suitable conditions, it has been found that they can be reared or cultivated artificially, and one of the most marked and important characters belonging to them is the enormous extent of self-propagating power they possess. This accounts for the rapid spread that is observed to take place of an infectious disease, if allowed to progress without controlling measures being brought to bear upon it. We have to deal, then, with something that lives and grows by virtue of a power pertaining to itself. Permit this living growth—this parasite, in fact—to become dispersed and to enter the system of a living person, and presuming it has lodged upon a soil supplying suitable conditions for its development, it will thrive and multiply and give rise to a series of phenomena which the physician has no power to arrest. Once the bacillus is implanted and the disease established, all that the physician can do is to see that the patient has fair play—that he is kept under the most favourable conditions for battling successfully against his enemy. What is to be philosophically aimed at, however, is to check the spread—to bar the transmission of the parasite from one person to another, by attacking it outside the body; and this, with the application of the proper measures of disinfection, can with facility be done, but naturally the facility of preventing extension stands in proportion to the degree of limitation at the time existing. The spark of fire is with the greatest ease extinguished, but let it kindle into flame, and in proportion as the flame spreads the difficulty becomes greater to get the conflagration under. This is one way in which the attack upon the bacillus may be made, and the ravages of disease restrained. Another way, by quite a different line of tactics, presents itself; and the knowledge of this is due to the researches that have been recently conducted. The vulnerable point to which I am alluding lies not in connection with the bacillus itself, but with the condition of the medium upon which it may chance to fall. It has been found that the parasite requires virgin soil for its growth. This observation stands in harmony with the result of common experience as regards disposition to contract infectious disease. It has been from remote times generally known that a person who has passed through one attack of an infectious disorder is not liable to the same extent as before to become affected on exposure to contagion. An influence has been exerted giving rise to more or less protection being afforded against a recurrence of the disease. Now it happens that by certain means the bacillus may be brought into such a weakened state as only to occasion, when introduced into the system of an animal, an effect of a mild nature, not dangerous to life, instead of the ordinary form of disease; but the effect produced, and this is the great point of practical importance, is as protective against a subsequent attack as the fully-developed disease. There are two methods by which attenuation in virulence of the disease-producing organism may be brought about—

by conducting their artificial cultivation in a particular way, and by transmission through the system of an animal differing in nature from that in which the disease naturally occurs. When the chain of discoveries reached the point of showing that bacilli could be reared outside the body in an artificial soil or cultivating medium, a great advance was made towards obtaining a full knowledge about them, as it placed the observer in a more favourable position for the successful prosecution of research by enabling him to vary and control his conditions in a manner that could not otherwise have been effected. Although much has been accomplished, it must be said much still remains to be done. In the case of a few bacilli the life-history has been pretty clearly made out. Cultivated in a certain way they retain their virulence, no matter through how many successions they pass. The last product in a series of successive cultivations is as virulent as the parent stock. By modifying the conditions under which the cultivation is carried on, the successive products of descent may be gradually weakened until they become harmless. Such being the case, any desired degree of attenuation may be obtained, and by inoculation with a virus brought down to the proper strength the non-fatal affection may be occasioned which gives immunity from subsequent liability to take the disease under exposure to contagion. The knowledge thus acquired has been already practically turned to account upon a large scale for checking the ravages of that exceedingly fatal disease among cattle known as anthrax, or splenic fever, and through the success attained much sacrifice of life has been averted. If this can be accomplished for one disease, and more than one can be mentioned, is there not ground for believing that means will be found for placing others of the class in the same position? Attempts are being made in this direction. All eyes throughout the civilised world are, indeed, at the present moment fixed upon the work of Pasteur in Paris with reference to hydrophobia. It would be a great achievement for this frightful disease to be brought under subjection, and certainly the results that have been obtained appear to give hopes that an approach to something of this kind has been arrived at. Looking at the nature of the disease, there is nothing inconsistent with its being dependent upon a bacillus, or microbe, as Pasteur calls it. On the contrary, owing its origin as it does, when occurring naturally, to inoculation with the poisoned secretion of an affected animal, and taking into view the facts that have been learnt in connection with its transmission by artificial inoculation, evidence points to such in reality being the case. If due to a bacillus, why may not this bacillus be open to attenuation in the same manner as that of anthrax? If thus open to attenuation, why not susceptible of producing a non-fatal form of affection? And if this condition has been produced and passed through, why should not protection be thereby given against the subsequent development of the disease as a result of the primary inoculation from the bite of the rabid animal? Such a train of reasoning is quite legitimate, and for the application of the principle of action to which it leads, there is this advantage on the side of hydrophobia, that from the prolonged period usually taken for incubation after the introduction of the poison in the ordinary way, time is given for the artificial inoculations by subcutaneous injection to produce their effect and to render the system refractory to the further development of disease. I have been an eye-witness of Pasteur's work. It is from the nerve centre, the seat from which the symptoms of the disease start, that he obtains his virus. Employed for inoculation in a fresh state it produces a fatal disease, and the disease has been transmitted successively on through a number of animals, with the result that the last affected animal yields as strong a virus as the first. Kept in a pure, dry air, attenuation advances, and after a certain time the nerve centre loses its disease-producing power. Used for inoculation at a given period of preservation it produces an effect which renders an animal resistant to the influence of inoculation with the virus in a fresh state, and Pasteur contends that it acts similarly when the virus has been introduced in the ordinary way. The treatment of persons bitten by rabid animals by inoculation with attenuated virus has now been on its trial a considerable time, and a large experience gained. Judgment, it must be stated, still stands in suspense; but it must also be said that the results obtained tell decidedly in favour of the view advanced. The other method by which it has been recently experimentally found that the virulence of bacilli can be weakened is by transmission through an animal of a different nature from that in which the disease naturally occurs. This, in reality, represents the principle at the foundation of the system of vaccination, discovered by Jenner at the close of the last century. It may now be regarded as an accepted conclusion that vaccine-lymph is the virus of small-pox modified by transmission through the cow. Jenner's discovery consisted in showing that the result of vaccination with the lymph of cow-pox affords as much protection against small-pox as an attack of small-pox itself. This was the fact he educed, but the knowledge possessed in his time did not permit of its being looked at in any further way than as a simple fact or truth of Nature. Viewed, however, with the light that has been thrown upon it by the researches of the present day, we see not only the fact, but also its explanation: we see that the principle of action of the procedure proposed by Jenner, which has conferred such incalculable benefit upon mankind, is based upon the attenuating effect upon the small-pox virus of the human species by transmission through another animal; and knowing this, the prospect is presented of its being rendered susceptible of application for the control of other diseases. Whether this should prove so or not, at all events advantage is gained by the knowledge acquired. Need I say anything more to exhort you, in accordance with the duty that has devolved upon me? Surely the acquirement of knowledge, giving us as it does greater power in the exercise of our calling, and thereby promoting the high and noble object of rendering our lives more useful to our fellow-creatures—surely this is a sufficient incentive, following the words of Harvey, 'to search and study out the secrets of Nature by way of experiment.'"

NOTE ON THE ASTRONOMICAL THEORY OF THE GREAT ICE AGE [1]

THE following calculation has convinced me that Mr. Croll's theory affords an adequate explanation of the Ice age. I compute the total quantity of heat received by each hemisphere of the earth during summer and winter respectively as follows:—

Let $2H/a^2$ be the quantity of sun-heat falling perpendicularly on an area equal to the section of the earth at the mean distance a from the sun in the unit of time.

Let δ be the sun's north declination. Then the share received by the northern hemisphere will be

$$\frac{H}{a^2}(1 + \sin \delta),$$

and by the southern

$$\frac{H}{a^2}(1 - \sin \delta).$$

At the distance r, and in the time dt, the heat received in the northern hemisphere will be

$$\frac{H}{r^2}(1 + \sin \delta) \,.\, dt;$$

but we have

$$r^2 d\theta = h dt,$$

whence the expression becomes

$$\frac{H}{h}(1 + \sin \delta) \,.\, d\theta;$$

but we have

$$\sin \delta = \sin \theta \,.\, \sin \epsilon,$$

where ϵ is the obliquity.

The total heat received by the northern hemisphere from the vernal to the autumnal equinox is

$$\int_0^\pi \frac{H}{h}(1 + \sin \epsilon \sin \theta) \,.\, d\theta = \frac{H}{h}(\pi + 2 \sin \epsilon).$$

We have thus the following theorem:—

Let $2E$ be the total sun-heat received in a year over the whole earth; then this is divided into shares as follows:—

$$\text{Northern hemisphere, summer, } E\frac{\pi + 2 \sin \epsilon}{2\pi},$$

$$\text{,, winter, } E\frac{\pi - 2 \sin \epsilon}{2\pi};$$

with identical expressions for the summer and winter in the southern hemisphere.

[1] Paper read at the Royal Irish Academy on May 24, 1886, by Sir Robert Stawell Ball, LL.D., F.R.S. Communicated by the Author.

If we make $\epsilon = 23^\circ 27'$ we find that the heat received during the summer (equinox to equinox) of each hemisphere is $\cdot 627\,E$, while the heat during the winter of each hemisphere is $\cdot 373\,E$. More briefly still. If each hemisphere receives in the year a quantity of sun-heat represented by 365 units, then 229 of these are during summer, and 136 during winter. These figures are independent of the eccentricity of the earth's orbit.

The length of the summer is defined to be the interval when the sun's centre is above the equator. The length will of course vary with the eccentricity and with the position of the equinoxes on the orbit. We need only take the extreme case where the line of equinoxes is perpendicular to the major axis of the orbit. The maximum difference between the length of summer and of winter is thus

$$365 \text{ days} \times \text{eccentricity}.$$

I take the maximum eccentricity of the earth's orbit to be

$$0\cdot 0745,$$

this being the mean of the values by Leverrier, Lagrange, and Stockwell (see Croll, "Climate and Temp.," p. 531), and, therefore, the greatest difference between summer and winter will be about 33 days, *i.e.* one season is 199 days, and the other is 166 days.

The total quantity of heat received during the year on each hemisphere is practically independent of the eccentricity; but the mode in which that heat is received at the different seasons will vary, and thus give rise to the following extreme cases:—

GLACIAL

(Summer)	229 heat units spread over 166 days.	
(Winter)	136 ,, ,, 199 ,,	

INTERGLACIAL

(Summer)	229 heat units spread over 199 days.	
(Winter)	136 ,, ,, 166 ,,	

We hence deduce the following, where unity represents the mean daily heat for the whole year on one hemisphere:—

GLACIAL

Mean daily sun-heat in summer (short) ...	1·38
,, ,, winter (long) ...	·68

INTERGLACIAL

Mean daily sun-heat in summer (long) ...	1·16
,, ,, winter (short) ...	·81

PRESENT (NORTHERN HEMISPHERE)

Mean daily sun-heat in summer (186 days)	1·24
,, ,, winter (179 days)...	0·75

These figures exhibit a thermal force of great intensity. The unit represents all the mean daily heat received from the sun by which the earth is warmed up from the temperature of space. The heat unit in fact maintains a temperature perhaps 300°, or even more, above what the earth would have without that heat. Each tenth of a unit may thus roughly be said to correspond to a rise or fall of mean temperature of 30° or more. The long winter of 199 days, when the average heat is only two-thirds of a unit, leads to the accumulation of ice and snow, which form the Glacial epoch. The short winter of 166 days, where the temperature is ·06 of a unit above that of our present winter, presents the condition necessary for the mild interglacial epoch.

THE BRITISH ASSOCIATION

SECTION H—ANTHROPOLOGY

The Native Tribes of the Egyptian Súdan, by Sir Charles Wilson, K.C.B.—These may be divided into four distinct groups—the Hamitic, Semitic, Núba, and Negro; but the first three only were dealt with in this paper. The largest tribe in the Súdan is the Kabbabish. They extend from Dongola to the confines of Darfúr; they speak a pure Koranic Arabic, and have a tradition that they came from Tunis; they are possibly of Berber descent, but the Sheikhs are apparently of Arab origin. They are divided into two great branches and several minor clans. One clan, Kawahleh, appears to be of Arab origin.

The Celtic and Germanic Designs on Runic Crosses, by Prof. W. Boyd Dawkins.—The author said that although it is generally assumed by archæologists that the early Irish manuscripts, such as the illuminated Gospels of St. Cuthbert and St. Chad, are of pure Irish art, and that consequently the interlacing "rope-" or "basket-work" pattern is distinctly Irish and Celtic, such an assumption is not warranted by experience. A consideration of the distribution of the designs on ornaments and monuments in the British Isles and in France, Scandinavia, and Germany, lead to the conclusion that the art was probably derived from the centres of civilisation in South Europe, principally Greek and Etruscan, and it has clearly been proved by Chantre to have been introduced into France from Italy. The square interlacing pattern does not occur in France or the British Isles in association with any remains of a date anterior to the movement of the Germanic tribes against the Roman Empire, and as it is only found in regions into which the German tribes penetrated, it may be concluded that it is distinctly Germanic, and not Celtic, still less "pure Irish."

The Scientific Prevention of Consumption, by G. W. Hambleton.—There are two distinct objects to be accomplished in the prevention of consumption. On the one hand we have to secure an adequate amount of breathing capacity in proportion to the rest of the body, and on the other to prevent either compression of the chest or injury to the lungs. This can be done by adopting those measures that tend to the development of the breathing capacity, and suppressing or obviating those conditions that compress or injure the lungs. By adopting measures is meant placing men, women, and children under conditions of habitation, clothing, education, and urging upon them habits that tend individually and collectively to develop the lungs.

Dragon Sacrifices at the Vernal Equinox, by George St. Clair, F.G.S.—The object of this paper was to show that human sacrifice, which prevailed extensively in early times, was a custom connected especially with the vernal equinox, and that the offerings were made to appease a mythical dragon which made its demand at that time. The dragon of mythology was identified and defined, and it was shown in what sense he opened his jaws at the spring season of the year. Human sacrifice was practised more especially at the spring of the year, or (in other instances) in honour of deities who once presided over equinox constellations. Artemis and Cronus, to whom this homage was chiefly shown, were both connected with the zodiacal sign Scorpio, and, according to M. Ernest de Bunsen, Scorpio was the starting-point of the primitive calendar. If the festival of Saturn did not get displaced or misplaced through the precession movement, it was still a festival in honour of the god of the under-world, and that meant death and the grave. Tradition says that human sacrifices were abolished by Hercules. As Scorpio rises with Hercules, and ceases to be a dark sign, the mythology is consistent with itself.

Evidence of Pre-Glacial Man in North Wales, by Dr. Henry Hicks, F.R.S. — The author in this paper described the conditions under which a number of flint instruments were discovered during the researches carried on by Mr. E. B. Luxmore and himself in the Ffynnon Beuno and Cae Gwyn Caves, in the Vale of Clwydd, in the years 1884–86. Last year a grant was made by the British Association for the purpose of carrying on the explorations, chiefly with the object of obtaining further evidence as to the age of the deposits in the caverns. The results obtained this year are highly confirmatory of the views which he (Dr. Hicks) had previously held, and have a very important bearing on the antiquity of man in Britain. It was found that the main entrance to the Cae Gwyn Cave had been blocked up by a considerable thickness of Glacial beds, which must have been deposited subsequently to the occupation of the cave by the Pleistocene mammals. A shaft was dug through these beds in front of the entrance to a depth of over 20 feet, and in the bone-earth, which extended outwards under the Glacial beds on the south side of the entrance, a small well-worked flint flake was discovered. Its position being about 18 inches beneath the lowest bed of sand, it seemed to be clear that the contents of the cavern must have been washed out by marine action during the great submergence in mid-Glacial times, and then covered by marine sand and an upper covering of boulder-clay. He believed that the flint implements, lance-heads, and scrapers found in the caverns were also of the same age as this flint flake, and hence that they must have been the work of pre-Glacial man.

The Recent Exploration of Gop Cairn and Cave, by Prof. Boyd Dawkins.—This was a paper on the exploration of Gop Cairn and Cave, near Gop Hall, New Market, St. Asaph, now being carried on by Mr. Pochin, Mr. P. G. Pochin,

and the author. The cairn commonly known as "Queen Boadicea's Tomb" was composed of blocks of limestone, about 40 feet high, 300 feet long, and 200 feet broad. A shaft was sunk near the centre of the cairn, but the only remains discovered were a few refuse heap bones of hog, sheep or goat, ox or horse, too fragmentary to be accurately determined. They were, however, of the character found almost universally in Britain in the burial-places of the Neolithic and Bronze Ages. The cairn itself was similar in character to one near Mold, in the same district, in which a skeleton was discovered in 1832 lying at full length, clad in a golden corselet, and adorned with 300 amber beads. An urn full of ashes and other remains was also met with. While the cairn was being attacked, a cave was discovered 141 feet to the south-west, and there were found bones and teeth of various animals which belonged to the Pleistocene age, and similar to those discovered in the caves of the Vale of Clwydd. Above these was found a deposit containing fragments of charcoal and large quantities of broken bones of wild and domestic animals. Slabs of limestone burned on their upper surface were also found, and pointed out the position of the fireplace. The date of this upper deposit was fixed by several fragments of pottery, which was in its characteristics similar to that of the Bronze Age. Besides these, a large number of human bones were found, increasing in number as the explorers dug their way to a square sepulchral chamber, 4 feet 10 inches by 3 feet 10 inches. This chamber was packed with human skulls and bones of all ages in the greatest confusion, and evidently interred from time to time. Among the bones were found two jet ornaments, a beautifully polished flint flake, with edges carefully bevelled, and some fragments of rude pottery of the kind commonly found in sepulchral urns of the Bronze Age. The chamber and the deposits showed that caves had probably been used for habitation and sepulture in North Wales in the Bronze Age, as they had already proved to have been used in the Neolithic Age. The human remains threw great light on the ethnology of the district in the Bronze Age, and proved that in the Neolithic Age the population of that part of Wales was of the oval-headed Iberic type, so widely spread throughout Europe. All the skulls were of this type save one, which possessed all the characteristics usually found in a round-headed Celt of the Bronze Age, and the presence of this skull in a sepulchre of the Iberic people appears to mark the beginning of the fusion of the two races, which has been going on ever since, and by which the Iberic type is at the present time being slowly obliterated.

On Bowls' Barrow, near Heytesbury, in South Wilts, by W. Cunnington.—These researches, the writer stated, had been made at the east end of the barrow, where the original cist had been found empty, but with a skull near it. Several other skulls were also found in a more or less broken condition. Covering the floor of the barrow near where the skeletons were found was a black unctuous earth, which had been found to contain a large quantity of ammoniacal salts. Separated from the cist at the east end of the barrow several horns of oxen had been found, in addition to those that were found there some years ago. The skulls and other human remains which had been found were clearly primary burials, and were covered by large blocks of Sarsen stone, some of which weighed from 200 lb. to 300 lb.

The Crania and other Bones found in Bowls' Barrow, by Dr. J. G. Garson.—The author said that the skulls are of large size, and long and narrow in form. In general outline they present two distinct forms, namely, the elongated oval, and what is called the coffin-shaped. They all conform in every respect to the long barrow type, and are all those of adult males.

Papuans and Polynesians, by the Rev. George Brown.—The object of this paper was to show that the two races had a common origin. Mr. Brown said he had worked for many years among the purest types of Polynesians and of Papuans, and in reducing the languages to writing he became convinced that, from the point of view of language and from their manners and customs, some of the difficulties in assigning to the two races a common origin were not so insuperable as they appeared. He considered that the basis of the Polynesian race was Papuan with an Asiatic admixture. The idea that cannibalism existed because of the love of animal food and the inability to gratify this appetite in any other way was all nonsense: in ninety-nine cases out of a hundred it was only practised as a means of revenge. The author gave a description of the etiquette and general manners and customs of the two peoples, and, summing up his argument, said the points of similarity were so much more numerous and marked than the points of difference that as they inquired further they would find no insuperable difficulty in giving them one common origin.

What is an Aryan? by Sir George Campbell, K.C.S.I.—The great difficulty which we had in distinguishing the Aryan was that the Aryan race was seldom pure. Almost all the Aryans we met with were a very mixed race, but by their features and colour they were easily distinguished from the Turanian and Negro races. The difficulty in distinguishing between the Aryans and the Semites lay in their features, and if the rather high features, which we called Jewish, were the real types of the Semites, what were the types of the Aryans? There were two distinct branches of Aryans with which he had long been in contact—the dark branch found in India and Asia, and the fair branch, which included the whole of Europe and Asia Minor. Then in part of Western Asia, in the Hindu Kush, there was a whitey-brown variety of the race, which might be classed as the intermediates, and this he believed to have been the original habitat of the Aryan race. The question, of course, was what was the original Aryan—white, brown, or whitey-brown? and he was inclined to think that he was a whitey-brown, and that his primæval seats were in the higher recesses of the Hindu Kush, and that the branch which went into India had become darker by admixture with the aborigines, while those who went into Europe had become fairer or been completely blanched into whiteness by similar admixture with the fair races. As to features, he had come to the conclusion that the high prominent features which we were accustomed to speak of as distinctive of the Semite races were the real original features of the Aryan, and that the Jews had acquired them only by admixture with the Aryan races. The true type of Semite he believed was to be found in the Southern Arab.

On the Influence of the Canadian Climate on Europeans, by Prof. W. H. Hingston, M.D.—After describing the physical, geographical, and climatic characteristics of the country, the author proceeded to say that the heat of the summer in Canada was more easily endured than the moist humid summer weather often experienced in Europe. The skin was called into greater activity, and the heat of the summer weather acted very strongly on the liver, but if European residents adopted the indigenous customs of the country, lived moderately and temperately, and led active lives, their livers would give them no trouble. The cold weather in winter stimulated people to activity. The mortality in early life was large, because in no country in the world were there so many children, but the mortality in adult life was not large. With the exception of Malta, the Canadian stations used to be considered the healthiest posts of the British army, and there were really no diseases peculiar to the country, while many which prevailed in England and in Europe had no existence there.

The Life-History of a Savage, by the Rev. George Brown.—The author gave an account of the life-history of a native of New Britain, an island in the Polynesian group, about forty miles north-east of New Guinea. He commenced with the birth of the example child, and said that when a child was born to the Papuan people who occupied this land, a warm banana-leaf was wrapped round his body, and he was fed with the expressed juice of the cocoa-nut, and left ever afterwards to be "dressed in pure sunshine." He described the children's games of the people, and the initiation of the boy as he grew up into certain secret rites, and the ceremonies at the various feasts, especially on his marriage, and the feast when he was taught to curse his enemies. On the occasion of his marriage there was an interchange of goods and a distinct payment for the wife. Presents were also given by the women to the bride and by the men to the husband, and after a broom had been given to the former, and a spear to the latter, a stick was given to the man. The spear meant that the husband was to protect his wife, and the broom that with it the wife was to do her household work, and the stick was a symbol of his authority, or, in plain English, "Here's the stick with which to whack her if she does not." At the time of death the cries of the friends of the deceased were very piteous and touching. The dead person was cried to to come back, was expostulated with for having left his friends, was entreated to say how his friends had offended him, and so on, the mourners seeming to be speaking in the very presence of the spirit of the dead person. Many of the things which we should call good they also called good, but they had a definite

idea of a future state and also of punishment for one offender, the niggardly man. When an old man came near death he was placed upon a litter, and carried round to see the old scenes amid which he had passed his life—his canoe, the sea, and all the old familiar subjects, and then he was taken back to wait his time. After death he was placed in a sitting posture and taken into the public square, with his weapons by his side, and before him the people placed offerings of their valuable goods and money.

Notes on Photographs of Mummies of Ancient Egyptian Kings recently Unrolled, by Sir William Dawson, F.R.S.—The photographs representing the mummies of Seti I., Rameses II., and Rameses III. were communicated by Dr. Schweinfurth, of Cairo. They are of great interest as enabling us to see the actual features of these ancient Egyptian kings, and to compare them with their representations on the monuments and with modern Egypians. It appears that the features of Seti are scarcely of Egyptian type, as represented either by the monuments of the older dynasties or by the present Egyptians; though, as Dr. Schweinfurth shows in a drawing accompanying the photographs, a similar style of countenance still exists among the Copts. It also appears that the features of Rameses II. strongly resemble those of his father, and are very like those of some of his statues. Both Seti and Rameses have narrow and somewhat retreating foreheads, and strongly developed jaws, indicating men of action rather than of thought; and both were men of great stature and bodily vigour, and seem to have lived to advanced ages.

Prehistoric Man in Manitoba, by Mr. C. N. Bell, F.R.G.S. (Winnipeg, Canada).—The author announced the existence in the Canadian North-West of sepulchral mounds, and pointed out the hitherto unknown fact that there is a continuous line of mounds from the mound-centres of the Mississippi River, down the Red River, to Lake Winnipeg. Human remains, much decayed, were found in the mounds, all buried by being placed on the surface under heaps of earth in which patches of charcoal and ashes frequently occurred, though no remains of funeral feasts, as bones, &c., were met with. Indians, when first met with, buried weapons with their warriors, but none were found in these mounds, though implements and ornaments of shell, bone, and stone were common, as well as pottery, which latter was unknown to the Indians of North-West Canada on the arrival of white emigrants. One mound had a floor of burnt clay and boulders, similar to the sacrificial mounds and altars of Ohio. Ornaments were found made of sea-shells, which must have been carried 1200 miles from their native waters. These mounds, from Lake Winnipeg to the Gulf of Mexico, were of the same character, and very likely were made by one race, though the whites found great diversity of mortuary customs prevailing among the Indian tribes inhabiting that great tract of country.

Notes on a Tau Cross on the Badge of a Medicine-Man of the Queen Charlotte Isles, by R. G. Haliburton.—Mr. Haliburton said this badge was noteworthy, as Queen Charlotte Isles form one of the most isolated groups of the Northern Pacific. They lie off the west coast of British Columbia. This symbol was used by the Indians on large sheets of copper, to which they assigned a high value, and each of which they called a *Tau*. The connection of that name with the symbol is warld-wide. Our T is simply the tau symbol, and is called *tee* or *tau*. The medicine-men represent the tau sometimes on the forehead. The ancients used to mark the captives who were to be saved with a tau or cross; Ezekiel refers to this, and the word he uses for "the sign" to be marked on the foreheads of them that are to be saved really is the "tau" or "cross." No one has divined why the *scarab* was so sacred. He was led to a solution by seeing an exaggerated *tau cross* on the back of a scarab. On looking into the Egyptian name for the scarab he found it to be *tore*, and that the sutures on the beetle form a tau cross. But the same name is applied to the same beetle by our peasantry—*tor-beetle* or *dor-beetle*. Wilkinson represents a god with a scarab for a head, one of the names of which was *Tore*. The use of the prehistoric or pre-Christian cross is world-wide.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE

OXFORD.—This term begins under a new official *régime*. Prof. Jowett, Master of Balliol, retires from the Vice-Chancellorship, and Dr. Bellamy, the President of St. John's College, succeeds to his place. The Master of Balliol's four years of office have seen several important reforms in which he bore a prominent part. Among them we may mention the alteration in Honour Classical Moderations, the disestablishment of the Examination in the Rudiments of Faith and Religion, the establishment of a University course for medical students, and the abolition of Pass Classical Moderations in favour of Preliminary Examinations for students of law, natural seience, and mathematics. The last reform, indeed, has not yet become law; but the necessary steps to complete the legislation are already taken, and the Statute will doubtless pass Convocation during the present term.

Scholarships in Natural Science are announced this term for competition at Balliol, Trinity, and Christ Church.

The following scheme of lectures in Natural Science is announced for the present term:—

Physics.—Prof. Clifton lectures on General Electricity, and Mr. Selby on Electrostatics treated Mathematically. Practical instruction in Physics is given in the Clarendon Laboratory by Prof. Clifton and Messrs. Walker and Selby.

At Christ Church, Mr. Baynes lectures on Fourier's Theorem. At Balliol, Mr. Dixon lectures on Elementary Light and Heat.

Chemistry.—Prof. Odling lectures at the Museum on the Benzoic Compounds. Mr. Fisher gives a course of Inorganic Chemistry, and Dr. Watts a course of Organic Chemistry. Practical instruction is given by the above, and by Messrs. Baker and Marsh.

At Christ Church, Mr. Vernon Harcourt gives a course of lectures on Inorganic Chemistry for the Preliminary Examination. Practical instruction is also given at the Christ Church and Balliol Laboratories.

Animal Morphology.—Prof. Westwood lectures on the Hexapod Arthropoda. Prof. Moseley lectures on Comparative Anatomy. Mr. Baldwin Spencer gives an elementary course on the same subject. Mr. Hatchett Jackson lectures on Comparative Embryology. Mr. Barclay Thompson lectures on the Osteology, Odontography, and Distribution of Mammals. Practical instruction is given by Prof. Moseley, Mr. Spencer, and Mr. Robertson.

Physiology.—Prof. Burdon-Sanderson lectures on Circulation, Respiration, and Bodily Motion. Mr. Dixey lectures on Histology; and Mr. Hatchett Jackson on Elementary Physiology. Practical classes are conducted by Messrs. Dixey and Gotch.

Human Anatomy.—Mr. A. Thomson lectures on the Central and Peripheral Nervous System, and Digestive System. He also gives demonstrations on Topographical Anatomy, and has a daily class for Dissection.

Medicine.—Dr. Darbishire gives demonstrations at the Radcliffe Infirmary, in Physical Diagnosis and Regional Anatomy, and Mr. Winkfield gives demonstrations in Surgical Diagnosis.

Botany.—Prof. Bayley Balfour lectures at the Botanic Garden on Vegetable Morphology and Physiology.

Mineralogy.—Prof. Story-Maskelyne lectures at the Museum on Minerals occurring in Lodes.

Geology.—Prof. Prestwich lectures at the Museum on the Principles of Geology.

Anthropology.—Dr. Tylor lectures on the Development of Culture, Sign Reading, &c.

Mr. A. L. Selby, B.A., Demonstrator of Physics in the Clarendon Laboratory, has been elected a Fellow of Merton College.

Mr. H. B. Dixon, M.A., of Trinity College, has been elected a Fellow of Balliol College.

SCIENTIFIC SERIALS

IN the *Journal of Botany* for August Mr. J. G. Baker concludes his notes on British Rubi, and Messrs. Roy and Bisset contribute the second and concluding part of their notes on Japanese Desmids (illustrated).—The number for September commences with an interesting and important paper by Mr. G. Massee, on the structure and functions of the subterranean parts of *Lathræa squamaria*, L. (also illustrated). He regards the plant as of saprophytic rather than parasitic habit, the disks or haustoria on which its parasitism depends being frequently entirely absent from old plants. In some instances, but not all, the roots are covered with the mycelium of a fungus similar to that described by Kamienski in the case of

Monotropa.—The instalment of Mr. J. G. Baker's synopsis of the Rhizocarpeæ is occupied by a monograph of the forty species of *Marsilea.*—The remaining articles in these and those in the October number are of less general interest, or are reprints or reports.

Rivista Scientifico-Industriale, September 15.—Experiments on the electric conductivity of vapours and gases, by Prof. Giovanni Luvini. The important experiments here described have been carried out for the purpose of exposing the commonly accepted fallacy that moist air and gases in general are good conductors. Having already argued against this view in his recent memoir on the origin of atmospheric electricity, the author now clearly shows by a series of carefully conducted experiments that such bodies as moist air, aqueous vapour, and other gases are under ordinary pressure absolute non-conductors. Under pressures varying from 16° to 100° C. none of the vapours tested by him betrayed the least conductivity, all acting as excellent insulators. He promises to resume the subject in his work on the Polar auroras, to which the present essay and the memoir on the origin of atmospheric electricity serve as introduction. The conclusions so far arrived at, combined with Faraday's memorable experiments on the causes of the electricity in Armstrong's hydro-electric machine, tend to show that gases and vapours are not even electrified by friction with themselves or with solid or fluid bodies. Henceforth physicists must reject, as erroneous, all such theories respecting the electricity of machines, of the air, or the clouds, as rest on the assumed conductivity of moist air or on the property of gases to be electrified by friction. It is pointed out that, were the saturated atmosphere and clouds really good conductors, such a phenomenon as lightning would be simply impossible, or at all events extremely rare.—Separation of nickel from cobalt, by Pietro Gucci. For the new method here proposed and described it is claimed that it is both easier and much more expeditious than that of Fischer and Stromeyer, also that it determines the presence of the smallest particle of nickel in any quantity of cobalt.—New hygrometric formula and tables, by Prof. Paolo Cantoni.

SOCIETIES AND ACADEMIES

LONDON

Entomological Society, October 6.—Robert McLachlan, F.R.S., President, in the chair.—Mr. W. Bartlett Calvert, of Santiago, Chili, was elected a Fellow.—Mr. McLachlan exhibited a number of seeds of a Mexican species of *Euphorbiaceæ*, popularly known as "jumping seeds," recently received by him from the Royal Horticultural Society. He stated that these seeds were known to be infested with the larvæ of a species of *Tortricidæ*, allied to the apple *Tortrix*. They were first noticed by Prof. Westwood at a meeting of the Society held on June 7, 1858, and the moths bred therefrom were described by him as *Carpocapsa saltitans*. These seeds have since, from time to time, been referred to both in the United Kingdom and America.—Mr. Roland Trimen exhibited and read notes on some singular seed-like objects found in the nests of *Termites*, and also in those of true ants, in South Africa. They were apparently of the same species as those from the West Indies, described in 1833 by the Rev. L. Guilding as *Margarodes formicarius*, which was usually referred to the *Coccidæ*. They were of various shades from yellowish pearly to golden and copper colour, and were strung together by the natives like beads, and used by them as necklaces.—Mr. W. F. Kirby exhibited, on behalf of Mr. John Thorpe, of Middleton, a long series of buff and melanic varieties of *Amphidasis betularia*, and read notes on them communicated by Mr. Thorpe.—Mr. Kirby also exhibited, on behalf of Mr. Nunney, a dark variety of *Argynnis aglaia* from Caithness, and a tawny-coloured variety of *Vanessa urticæ* from Bournemouth.—M. Alfred Wailly exhibited a fine series of Saturnias and other Bombyces, mostly bred by him, from South Africa; also specimens of *Dirphia tarquinia*, *Attacus orizaba*, *Platysamia cecropia*, *P. ceanothi*, *Callosamia angulifera*, and *C. promethæa*, from Central America. M. Wailly stated that several of the large South African *Saturnidæ* formed no cocoons, the larvæ entering the earth to undergo the change to the pupal state. Mr. Trimen said he was able to confirm this statement.—The Rev. W. W. Fowler exhibited a number of minute *Acari* which had been doing injury to fruit trees near Lincoln.—Mr. Poulton gave an account of the experiments recently made by him with the larvæ of several species of the genus *Vanessa*, for the purpose of ascertaining the relations of pupal colour to that of the surface on which the larval skin was thrown off, which had formed the subject of a paper lately read by him before the British Association. He also exhibited the frame constructed by him for the purpose of these experiments.—Mr. Slater exhibited a specimen of *Prionus coriarius* found in Devonshire on fennel, and a specimen of *Calandra palmarum* from Pembroke Dock.—Mr. Enock exhibited *Mymar pulchellus*, and a specimen of *Atypus piceus* recently taken on Hampstead Heath.—Mr. Elisha exhibited a series of *Gelechia hippophaella*, bred from larvæ collected at Deal on *Hippophaë rhamnoides*.—Mr. Billups exhibited *Echthrus lancifer*, a species of *Ichneumonidæ* new to Britain, taken at Walmer on August 15 last. He remarked that Brischke had bred members of this genus from *Sesia sphegiformis*, *S. formicæformis*, and *Leucania obsoleta*; but that in this country the genus was little known, only one species being mentioned in Marshall's list of *Ichneumonidæ*.—Mr. E. A. Butler exhibited living specimens of *Chilacis typhæ*, received from the Rev. E. N. Bloomfield, of Guestling, Hastings; and a pair of *Harpalus discoideus*, obtained in August last, near Chilworth, Surrey.—Mr. A. J. Rose exhibited specimens of a mountain form of *Lycæna virgaureæ*, recently collected by him in Norway.—Mr. Champion exhibited *Teratocoris antennatus* and *Drymus pilicornis*, taken near Sheerness.—Mr. W. White exhibited a specimen of *Chelonia caja* with abnormal antennæ, and read notes on the subject.—Mr. Elisha read a paper on the life-history of *Geometra smaragdaria*.—Mr. C. O. Waterhouse communicated a paper on the tea-bugs of India and Java.

SYDNEY

Linnean Society of New South Wales, Aug. 25.—Prof. W. J. Stephens, M.A., F.G.S., President, in the chair.—The following papers were read:—Note on *Eucalyptus leucoxylon* (F. v. M.), by W. Woolls, Ph.D., F.L.S. In the "Flora Australiensis," vol. iii., two Eucalypts previously regarded as distinct species (*E. leucoxylon*, F. v. M., and *E. sideroxylon*, A. Cunn.) were united under the former name. Dr. Woolls has long thought that this step was a mistake, and in his paper he gives reasons based upon the examination of specimens of both forms, in favour of their specific distinctness, and of the restoration of Cunningham's name to the red-flowering iron-bark of New South Wales, the other name being restricted to the white gum of Victoria and South Australia.—Contributions towards a knowledge of the Coleoptera of Australia, No. III., by A. Sidney Olliff, F.E.S. This paper contains notices of several new species of *Nascio*—a genus of Buprestidæ—of which two are named *L. munda* and *N. multesima*. Additional localities for some previously known species are also given, *N. carissima* being recorded from Sydney.—List of the Orchideæ of the Mudgee District, by Alex. G. Hamilton. In this paper, which is a contribution towards a knowledge of the geographical distribution of plants in New South Wales, fifty-seven species of orchids are enumerated as occurring in the Mudgee District; and particulars are given concerning their habitats and the months during which they flower. In addition a comparison of the orchids of this district with those of the county of Cumberland and of the other Australian colonies is also given.—On an undescribed species of *Chilodactylus* from Port Jackson, by E. P. Ramsay, LL.D., F.R.S.E., and J. Douglas Ogilby. Under the name of *Chilodactylus polyacanthus*, a new species of Morwong is described, and its affinity to *C. carponemus*, Cuv. and Val., is discussed.—Dr. Ramsay exhibited a number of very rare birds from Derby, North-West Australia, recently collected in that district by Mr. Cairns. He particularly drew attention to the following:—*Poephila acuticauda*, *Poephila mirabilis*, *Donacicola pectoralis*, *Emblema picta*, *Estrelda annulosa*, *Estrelda ruficauda*, *Pœcilodryas cerviniventris*, *Smicrornis flavescens*, *Pardalotus rubricatus*, *Pardalotus uropygialis*, *Malurus coronatus*, *Malurus cruentatus*, *Cacatua gymnopis*, *Climacteris melanura*, *Geophaps albiventris*, *Astur cruentus*, *Trichoglossus rubritorquatus*.—Mr. Macleay exhibited the following new or rare reptiles and fishes collected by Mr. W. W. Froggatt in the vicinity of Cairns, Queensland:—Snakes: *Tropidonotus picturatus*, Schlegel, *Dipsas boydii*, Macleay, *Hoplocephalus assimilis*, Macleay, *Hoplocephalus nigrostriatus*, Krefft, *Nardoa crassa*, Macleay, and *Dendrophis bilorealis*, Macleay. Lizards: *Varanus ocellatus*, Gray, *Varanus*, sp. ?, *Hinulia*, n. sp., four species of Geckotidæ unknown, one with tail of remarkable width, and several other unknown lizards. Fishes: *Dules Haswellii*, Macleay, *Aristeus rufescens*, Macleay,

Serranus lanceolatus, Bleek, a species new to Australia, and a species of *Eleotris*, probably undescribed, remarkable for its minute scales. Collected from the same district were a number of frogs, among which Mr. Fletcher pointed out examples of *Hyla dolichopsis*, *H. cærulea*, *H. lesueurii*, *H. peronii*, *H. nasuta*, *H. gracilenta*, *Limnodynastes ornatus*, and two other species not determined.

PARIS

Academy of Sciences, October 11.—M. Jurien de la Gravière, President, in the chair.—On a principle in rational mechanics, and on a demonstration used by Daniel Bernoulli in 1757, by M. de Jonquières. The reference is to the author's recently-explained theory of the hydro-extractor, the fundamental principle of which he now finds was already known to Bernoulli, at least so far as concerns the action of the pendulum. His demonstration, analogous to that of M. de Jonquières, is contained in his memoir entitled, "Principes hydrostatiques et méchaniques, &c.," which obtained the prize of the Royal Academy of Sciences.—On the persistence of the instinctive functions and voluntary movements in bony fishes after extraction of the cerebral lobes, by M. Vulpian. In supplement to his previous paper on this subject, the author mentions the case of a carp operated upon on March 18, 1886, and which survived till September 29. During this period it acted in almost every respect like any ordinary fish, noticing and avoiding obstacles, seizing and swallowing its food, rejecting non-alimentary substances, and so on. With the exception of smell, it evidently retained all its senses and instinctive and intellectual faculties. This experiment fully confirms the results already determined by the researches of M. Is. Steiner, and shows that in fishes instinct and will survive the extraction of the cerebral lobes, which in reptiles, birds, and mammals are the seat of those faculties.—Experimental researches on the nature of *rigor mortis*, by M. Brown-Séquard. The object of these studies is to show that the rigidity ensuing after death is due neither altogether nor even to any great extent to the coagulation of the albuminous substances of the muscles, as still maintained by most physiologists on the authority of Brücke, Kuhne, and Wundt.—On the temperature of the bed of oceanic basins compared with that of the continents at the same depth, by M. Faye. In connection with the reference made to this subject in the opening address of the President of the British Association at Birmingham, the author takes the opportunity of generalising the law already established by him respecting the more rapid and deeper cooling of the earth's crust under the seas than under the continents. Not only is this law applicable to the Polar seas, whose lowest depths have a temperature very near zero, but also to those which do not freely communicate with the Poles. In these waters also the temperature decreases with the depth, the difference between them and the continents at the same depths being, within about 15°, as great as for the oceans.—Purification of yttria, by M. Lecoq de Boisbaudran. In the process of purification here described the earth A, differing little from that of M. Clève, yielded a beautiful phosphorescence of a pink auroral tint, due not to the yttria itself, as supposed by Mr. Crookes, but to the presence of a minute trace of bismuth derived either from the primary substance or from the reagents.—Fluorescence of the compounds of bismuth subjected to electric effluvium *in vacuo*, by M. Lecoq de Boisbaudran. In this paper the author sums up his observations on the pink fluorescence referred to in his previous communication. He remarks incidentally that during these studies he detected traces of bismuth in numerous chemical products, several of which were supposed to be quite pure.—Summary of the meteorological observations made during the year 1885 at four stations in the Upper Rhine and Vosges districts, by M. Hirn. The observations here tabulated give the highest and lowest temperatures from month to month at Colmar, Thann, Schlucht, and Munster, the actinometric readings taken at the Colmar Observatory, the atmospheric pressure, rainfall, and other meteorological data at these stations.—On the transformation of surfaces, and on a class of differential equations, by M. E. Picard.—The reciprocal relations of the great forces of Nature, by M. Emile Schwœrer. The author's remarks are in reference to his French translation of M. A. Klein's remarkable analysis of MM. Hirn and Clausius's recent memoirs contributed to *Gaea*.—Saturation of normal arsenic acid with lime-water and with the water of strontian, by M. Ch. Blarez.—Contribution to the study of the alkaloids, by M. Oechsner de Coninck. Two very sensitive reagents are described, which are easily produced, and which are likely to prove very serviceable in the diagnosis of the various alkaloids and of the different bases treated by the author.—On the genus *Entione*, Kossmann, by MM. A. Giard and J. Bonnier. In the *Porcellana longicornis* of Concarneau the authors have discovered an *Entoniscus* closely allied to those met by Fritz Müller in the Porcellanæ of the Brazilian seaboard. The study of this species, here named *Entoniscus mülleri*, justifies the division of the genus proposed by Kossmann. The term *Entoniscus* being reserved for the two species of parasites of the Porcellanæ, the *Entoniscus* of the crabs would then constitute the genus *Entione*.—Diseased grapes in the vineyards of La Vendée, by M. Prillieux. The vineyards of this district have this year been attacked by a species of mildew here fully described.—On some garnet-bearing rocks of Puy-de-Dôme, by M. Ferdinand Gonnard. It is shown that, contrary to the received opinion, the important group of garnets, whether as a mineralogical accident, or as an essential constituent element of the different grenatites, is largely represented in the primitive or plutonic formations of Puy-de-Dôme.—On the phosphated deposits of Beauval (Somme), by M. Stanislas Meunier. From a careful study of the phosphate of lime recently discovered at Beauval, the author infers that the phosphated chalk of Picardy belongs to an older geological epoch than that of Belgium.

HISTORY OF ETHICS

Outlines of the History of Ethics for English Readers. By Henry Sidgwick, Knightbridge Professor of Moral Philosophy. (London: Macmillan and Co., 1886.)

FROM the earliest times of Greek thought the foremost philosophic minds of Europe have restlessly sought for sanctions of the moral code; and the last quarter of the nineteenth century sees but little unanimity of opinion on the subject. The purely intuitional moralist dreads, in the determinist ethics of evolution and of utilitarianism, the deathblow of virtue properly so called. The followers of Bentham and of Spencer foresee the downthrow of morality unless some sanction more solid than the intuitionalist can supply be found for the ethical creed, unless "morality be established on a scientific basis." Neither can bring himself to understand how the creed of the other can really influence conduct; and both believe in their inmost hearts that the conduct of the other is really determined by something that goes deeper than the outward profession of faith.

Amidst the divergencies of ethical opinion, however, practical morality has undergone but little modification. Notwithstanding the momentous change wrought by the introduction of Christianity into Europe the ideal at which the good man aims to-day differs but little from that towards which the ancient Greek directed his endeavours. It is true that the Christian virtue of *humility* takes the place of the Greek *highmindedness;* but it is questionable whether the standard of excellence practically set before himself by the bishop who preaches the one differs materially from that of the philosopher who inculcated the other. This uniformity of practice amid diversities of faith, notwithstanding that the practice is in a high degree the outcome of the faith, receives perhaps sufficient explanation when it is remembered that the conduct of the individual is determined by a triple service—the service of Self, the service of Man, and the service of God. But the service of God—mediæval monkism notwithstanding—takes practical expression in every-day life in the service of Man, while the pure service of Self is rendered impossible by the exigencies of the social life. In this way conduct is practically reduced to a subtle compound of Egoism and Altruism. Whether the welfare of others is sought from motives of self-interest, or the improvement of self is ennobled by the thought that in this way the level of humanity is being raised, matters not practically. The material morality is the same, however wide may be the essential and formal difference.

But man is an inquiring animal, especially in the scientific and philosophical varieties of the genus. He cannot rest content with the mere possession of moral intuitions, he must also endeavour to ascertain their cause and mode of origin. He is also in his higher developments essentially a rational animal. He is not satisfied with the promptings of ethical desires, he must also justify the resulting conduct on rational grounds. Hence the science of ethics, which deals with the questions "What is right?" and "Why?"

In Prof. Sidgwick's "Outlines of the History of Ethics" we have a remarkably clear and succinct account of the answers that have been given to these questions. In dealing with the subject as a separate province of thought there is this peculiar difficulty, that ethical theory is in a very high degree determined by philosophic creed. The ethical theory of the Platonist for whom the Universe has thought itself out from the abstract to the concrete, inevitably differs from that of the modern evolutionist who believes that material and mental groupings have gradually advanced from the simple to the complex until the extraordinary complexity of the human brain and human thought-processes has been reached. Prof. Sidgwick has met this difficulty as fully as the space at his disposal rendered possible, and by not unduly narrowing the limits of his province has presented a tolerably complete bird's-eye view of the history of ethical thought.

His work begins with an *Introduction* intended to assist the reader in grasping and arranging the somewhat compressed historical matter presented to him in the body of the book. The student who comes fresh to the subject will probably find the study of this introduction more valuable at the end of his first perusal of the work than at the outset of his labours. Then follows in Chapter I. a general account of ethics, in which the subject is defined, and its relations to theology, politics, and psychology are clearly indicated. It may be useful to give here the "summary view of ethics" with which this chapter closes:—

"The subject of Ethics, most comprehensively understood, includes (1) an investigation of the constituents and conditions of the Good or Well-being of men considered individually, which chiefly takes the form of an examination into the general nature and particular species of (*a*) Virtue or (*b*) Pleasure, and the chief means of realising these ends; (2) an investigation of the principles and most important details of Duty or the Moral Law (so far as this is distinguished from Virtue); (3) some inquiry into the nature and origin of the Faculty by which duty is recognised, and, more generally, into the part taken by Intellect in human action, and its relation to various kinds of Desire and Aversion; (4) some examination of the question of human Free Will. It is connected with Theology, in so far as a Universal Good is recognised, inclusive of Human Good, or analogous to it; and again, so far as morality is regarded as a Code of Divine appointment. It is connected with Politics, so far as the well-being of any individual man is bound up with the well-being of his society; and again with Jurisprudence (or Politics), so far as morality is identified with Natural Law. Finally almost every branch of ethical discussion belongs at least in part to Psychology; and the inquiries into the origin of any moral faculty and the freedom of the Will are purely psychological."

The three following chapters form the main body of the work. The first deals with Greek and Græco-Roman ethics. In this chapter the author brings out clearly the Socratic paradox, that men's ignorance of justice is the sole cause of their unjust acts, that, in a word, no one is voluntarily bad; and its justification as the outcome of a pair of apparent truisms, (1) that every one wishes for his own good, and would get it if he could, and (2) that those who knew how to do just and righteous acts would prefer nothing else, while those who did not know could not do them if they would. Unfortunately, as a practical fact, men too often desire in their moments of passion what in

their hours of reflection they know to be wrong. And since action takes the line of least resistance at the moment of temptation, there follows remorse in the hour of bitter remembrance. In the moment of trial, knowledge of right is not absent but submerged. The development of ethical doctrine as it passed through the hands of Plato and Aristotle, of Zeno and Epicurus, is treated with marked clearness and ability.

In the chapter on Christianity and mediæval ethics the main characteristics of Christian morality occupy a considerable space, the only writer whose doctrines are expounded at any considerable length being Thomas Aquinas.

The last chapter deals with modern ethics, chiefly English. The author, however, tells us, in his preface, that he has not attempted to deal with contemporary modes of ethical thought—with which he has been engaged controversially—except in a very brief and summary way. The motive is admirable; but the fact is to be regretted. As a "manual for students" the book would have been more complete had contemporary ethics formed the subject of a concluding chapter. There are many who will take up this book as a summary of the subject as a whole from the hands of one of its masters, and who will be disappointed to find so meagre an account of modern transcendental ethics and of the moral theory as "sanctioned" by evolution. The writer who has treated the ethics of twenty centuries with such marked impartiality could safely have been trusted to preserve a due "objectivity" of treatment in dealing with the modes of ethical thought in his own time.

All genuine students of human thought and endeavour will thank Prof. Sidgwick for having presented them with this altered and enlarged edition, in a handy form, of his article in the "Encyclopædia Britannica."

C. Ll. M.

PROFESSOR CHRYSTAL'S "ALGEBRA"

Algebra: an Elementary Text-Book for the Higher Classes of Secondary Schools and for Colleges. By G. Chrystal, M.A. Part I. (Edinburgh: Adam and Charles Black, 1886.)

"THERE are few things where the want of an enlightened scientific public strikes an expert more than the matter of scientific text-books." "For our teaching of algebra, I am afraid, we can claim neither the sanction of antiquity nor the light of modern times. Whether we look at the elementary, or at what is called the higher teaching of this subject, the result is unsatisfactory. . . . In the higher teaching, which interests me most, I have to complain of the utter neglect of the all-important notion of algebraic form." "The logic of the subject, which, both educationally and scientifically speaking, is the most important part of it, is wholly neglected. The whole training consists in example-grinding. What should have been merely the help to attain the end has become the end itself. The result is that algebra, as we teach it, is neither an art nor a science, but an ill-digested farrago of rules, whose object is the solution of examination problems." "The problem for the writer of a text-book has come now, in fact, to be this—to write a book so neatly trimmed and compacted that no coach, on looking through it, can mark a single passage which the candidate for a minimum pass can safely omit. . . . When our system sets such mean ends before the teacher, and encourages such unworthy conceptions of education, is it to be wondered at that the cry arises that pupils degenerate beneath even the contemptible standards of our examinations. . . . The cure for all this evil is simply to give effect to a higher ideal of education in general, and of scientific education in particular. Science cannot live among the people, and scientific education cannot be more than a wordy rehearsal of dead text-books, unless we have living contact with the working minds of living men."

Such being some of the author's weighty utterances in his famous British Association address to Section A (NATURE, vol. xxxii. pp. 446-449), it was with much interest we read the announcement that he was writing a treatise on algebra, and it is with much pleasure we have perused this first instalment of 542 pages. This is no ordinary treatise: school text-books abound, and more are on the way. This bears traces everywhere of a master's genius; those are but clever arrangements of well-known materials.

This is an elementary volume because "it begins at the beginning of the subject"; it is not written, however, for babes. It will have been noticed how the address quoted above insisted upon the "all-important notion of algebraic form": at the commencement Prof. Chrystal lays down generally the three fundamental laws, and thence proceeds deductively. This he does because this idea of algebraic form is "the foundation of all the modern developments of algebra, and the secret of analytical geometry, the most beautiful of all its applications." The following abstract of the interesting preface will best indicate the writer's aim. Outside algebra proper the reader is expected to be familiar with the definition of the trigonometrical functions, and to have a knowledge of their fundamental addition-theorem. The first object is to "develop algebra as a science, and thereby to increase its usefulness as an educational discipline." Sources of information are indicated, and a most admirable feature is the introduction of numerous historical notes. With regard to some of the early chapters, which are specially hard reading for junior students, Prof. Chrystal writes that they were "written as a suggestion to the teacher how to connect the general laws of algebra with the former experience of the pupil. In writing this chapter I had to remember that I was engaged in writing, not a book on the philosophical nature of the first principles of algebra, but the first chapter of a book on their consequences."

The subject is broken up into twenty-two chapters, and, as the arrangement—"the result of some ten years' experience as a University teacher"—deviates somewhat from ordinary usage, we give the headings:—(1) Fundamental laws and processes (association, commutation, and distribution, with historical note); (2) laws of indices, theory of degree; (3) theory of quotients, first principles of theory of numbers; (4) distribution of products (Σ and Π,) principle of substitution, homogeneity, symmetry, principle of indeterminate coefficients; (5) transformation of the quotient of two integral functions; (6) G.C.M. and L.C.M.; (7) factorisation of integral functions;

(8) rational fractions; (9) continuation of theory of numbers (Lambert's theorem); (10) irrational functions; (11) arithmetical theory of surds; (12) complex numbers; (13) ratio, proportion, variation; (14) on conditional equations in general (elimination, transformation); (15) variation of a function; (16) equations and functions of first degree (determinants, contour lines); (17) equations of the second degree; (18) general theory of integral functions (Newton's theorem, Lagrange's interpolation formula, maxima and minima); (19) solution of problems; (20) arithmetic, geometric, and allied series; (21) logarithms; (22) theory of interest and annuities. There is a large collection of exercises: with regard to these, after reading the address, we are prepared to find that the author deprecates the idea of a reader's working through all these at the first reading: they are given for the sake of variety, and to be worked at different times of reading. Answers are given at the end. We have put the writer's own words in the forefront, that our readers may be reminded of what he has said in the past and informed of what he has now attempted to do. The result is a work of singular ability and freshness of treatment. It follows no previous leader, it will give rise to shoals, possibly, of imitators, but it will bear boiling down by the "fifth-rate workmen" whom the Professor lashes. It is not a book for our elementary classes, but it will be an excellent work to put into the hands of some of our sixth-form pupils. It is admirably adapted for thoughtful students at our Universities who have not the dread of examinations before their eyes, but can afford to go deeper into the subject than the ordinary run of our students do. The book is excellently printed and is of a handy size. We hope the second part is well advanced.

THE MAMMALS OF CENTRAL AMERICA

Biologia Centrali-Americana. Mammalia. By Edward R. Alston. With an Introduction by P. L. Sclater, M.A., F.R.S. 4to. (London: R. H. Porter, 1879–82.)

THE progress of various portions of the great work upon the fauna and flora of Central America undertaken by Messrs. Salvin and Godman has been from time to time noted in our columns. Each section of the extensive and almost exhaustive mass of material which the industry and liberality of the projectors and editors of the work have accumulated, has been placed in the hands of some one specially qualified to render them available for the purposes of science. No one could have been found more fitting to undertake the description of the mammals than the late Edward R. Alston, whose lamented and untimely death deprived zoology of one whose careful and conscientious method of work gave promise of a career of great benefit to the progress of the special branch to which he had devoted himself. He was unfortunately unable even to complete the work under review, which owes its finishing touches to the pen of Mr. Sclater.

Compared with the general mammalian fauna of the world, that of the region treated of by Mr. Alston is rather limited. 181 species are enumerated, of which 52 are Bats, and 60 Rodents. Of the *Primates*, 10 species of *Cebidæ* and 1 of *Hapalidæ* are described, all forms proper to the Neotropical region. Their extension into Central America is a subject of much interest which has been particularly investigated by Mr Sclater, whose observations are extended or confirmed by Mr. Alston. One species only (*Ateles vellerosus*) is known to inhabit Mexico, reaching as far north as the 23rd parallel. The *Insectivora* are represented only by 5 small species of *Soricidæ*. The *Carnivora* are more numerous. The *Felidæ* comprise the southern Jaguar, Ocelot, Margay, Eyra, and Jaguarondi, the widely distributed Puma, and the northern Bay Lynx. The dogs are all northern forms, viz., *Canis lupus*, *C. latrans*, and *Vulpes virginianus*. The *Mustelidæ* are well represented by both Neotropical and Nearctic forms. The two North American Bears, *Ursus horribilis* and *U. americanus*, both extend as far as Northern Mexico, and are therefore included within the scope of the work. But the most interesting of the *Carnivora* are the curiously generalised group of *Procyonidæ*. Of 8 recognised species of this family, 7 are included in the limits of Central America, the Brazilian *Nasua rufa* being the one exception. Of special interest are the rare and little known *Bassaris astuta* and *B. sumachristi* (of which a new figure is given), and *Bassaricyon gabbi*. The *Ungulata* are, as is well known, very poorly represented in the actual fauna of the American continent, though so abundant and varied in former ages. Four deer of the genus *Cariacus*, the northern Big-Horn and Prong-buck, two Peccaries and two Tapirs are all that can be mustered as denizens of the Central American region. It should be mentioned that the distinguishing cranial characters of Dow's Tapir are carefully worked out and figured. A fair proportion of the essentially Neotropical Edentates and Marsupials extend beyond the Isthmus of Panama, including the three modifications of the Anteater type, an Armadillo, three Sloths, and seven Opossums.

The Cetacea of the coast are not included in the work, but there is a full notice of the Manatee, containing copious extracts from Dampier's quaint but graphic description of the habits and distribution of the animal in his time. As in so many other cases, the correct scientific designation of this creature is a matter of considerable perplexity. We quite agree with Mr. Alston in keeping *Manatus* for the generic name, but *australis* can hardly be accepted for any of the species at present discriminated. It was originally applied to a combination of the African and American forms, as opposed to *borealis*, the northern Manatee or Rhytina, and if retained should belong to the former, as the African habitat is mentioned first by Gmelin (1788) and Tilesius (1812), and is the only one given by Shaw (1800). Cuvier (1809) first distinguished the African from the American species by their osteological characters, calling them respectively "Lamantin du Senegal" and "Lamantin d'Amérique," which names were subsequently Latinised by Desmarest (1817) into *M. senegalensis* and *M. americanus*. This last name is therefore certainly preferable to *M. australis* for the West Indian animal. In a recent monograph of the genus, Dr. C. Hartlaub (*Zoologische Jahrbuch*, Bd. I.) has carefully investigated the synonymy, and admits two species as inhabitants of the New World, *M. latirostris* (Harlan) and *M. inunguis* (Natterer), *M. americanus* being suppressed as a compound of the two. The Central American form is referred by Hartlaub to *M. latirostris*,

M. inunguis being apparently confined to the upper waters of the Amazon and Orinoco; but we cannot say that we are quite satisfied with the supercession of Cuvier's name for that of Harlan.

The work is illustrated by twenty excellent coloured plates by Wolf, Keulemans, and Smit, representing new or little-known species. We cannot conclude our notice without again expressing our admiration for the scientific enthusiasm and public spirit shown by Messrs. Godman and Salvin in the manner in which they are carrying out their great undertaking. W. H. F.

PACKARD'S "FIRST LESSONS IN ZOOLOGY"

First Lessons in Zoology, adapted for Use in Schools. By A. S. Packard, M.D., Ph.D., Professor of Zoology and Geology in Brown University. American Science Series, Elementary Course. (New York: Henry Holt and Company, 1886.)

ONE of the principal objects of the American Science Series, we are told, is to supply "authoritative books the principles of which are, so far as is practical, illustrated by familiar American facts." Another "lack" intended to be supplied by the series is that of text-books which "do not *at least contradict* the latest generalisations." Whatever success Dr. Packard may have attained in the first of these objects, we fear he has not always kept clear of the many pitfalls into which writers of compilations in any branch of science are in these days nearly sure to stumble. Some of his statements are certainly in contradiction to the latest generalisations of zoological science.

On p. 28 we find, in the account of *Millepora*, two forms of zooids, distinguished as "nutritive" and "reproductive." The so-called "reproductive" zooid is nothing of the kind, but simply a tentacle-bearing zooid unprovided with mouth and stomach. Its function is to assist the nutritive or gastro-zooids in obtaining nutrition, by directing small particles of food towards the latter Of the reproduction of *Millepora* nothing is yet certainly known, but Prof. Moseley has suggested that it may probably give off a free-swimming *Medusa*.

Again our author, in enunciating the differences of animals and plants, states (p. 6) that plants "inhale carbonic acid gas, and exhale oxygen," and that animals do just the reverse. This seductive and oft-repeated antithesis is unfortunately not strictly accurate. Both plants and animals inhale oxygen and exhale carbonic acid gas. But in the case of the chlorophyll-bearing plants this process is obscured by an opposite process, by means of which the carbonic acid gas (CO_2) is broken up into its constituent elements, the carbon (C) is absorbed into the plant, and the oxygen (O_2) is set free. This process is, however, rather a nutritive than a respiratory process.

Speaking of *Amphioxus* (p. 139) Dr. Packard states that the water after passing through the gill-slits "enters the general body-cavity." This is an error: the water enters the *peribranchial* cavity—a perfectly distinct structure of quite different origin. Nor has *Amphioxus* "two eye-spots," but only one.

In the chapter (XXIII.) upon the "Lung-fish" (*scr.* Lung-*fishes*), the African *Protopterus annectens* seems to have been mixed up with *Polypterus bichir*, which does not belong to this order at all. The former fish is correctly figured (p. 168), but is named *Polypterus* just above, and is stated to be found in the "Nile," which is the case with *Polypterus*, but not with *Protopterus*.

These inaccuracies occur to us as we turn over the leaves of the "First Lessons in Zoology": we fear it would not be difficult to find others. We must also say that the woodcuts are mostly of coarse execution, and not always well drawn. On the other hand, it may be allowed that as great, or greater, faults might be found with every other attempt that has yet been made to supply a school-book of zoology. We are not acquainted with a really satisfactory work of this kind. A good text-book of zoology for beginners has still to be written. In the meanwhile, Dr. Packard's "first lessons," although going rather too deeply into certain portions of the subject, may be use fully employed for this purpose, without fear of teaching much that will have to be unlearnt.

OUR BOOK SHELF

Russland: Einrichtungen, Sitten, und Gebräuche. Geschildert von Friedrich Meyer von Waldeck.
Die Schweiz. Von Prof. Dr. J. J. Egli. (Leipzig: G. Freytag, 1886.)

THESE volumes are amongst the latest of that encyclopædic work, "Das Wissen der Gegenwart," which has now passed its fiftieth volume. Although, so far as the publication has at present gone, there are more volumes devoted to popular descriptions of countries than to any other, yet general scientific subjects are by no means unrepresented. Thus, volumes have appeared on meteorology; insects, useful and injurious; the sun and planets; light and heat; the fixed stars; the earth and the moon; comets and meteors; electricity and its applications; the nourishment of plants; sound; the ocean, &c., &c. The series is progressing rapidly, we are glad to see, with very short intervals between the successive volumes, from which it is to be presumed that the undertaking is meeting with the success which it deserves amongst the German people, although, we regret to believe, it would ruin any publisher who projected and attempted to carry out a series of this scope and magnitude in this country. In both of the volumes before us the work appears to be done as thoroughly as the space admits Herr Meyer von Waldeck's book is the second part of a work on Russian laws, customs, and manners, and specially deals with the system of administration, and national defence, the church and clergy, and the grades of society. Prof. Egli's account of Switzerland contains a large amount of information compressed with much skill into a very small space. It is not merely a tourist's book, although the tourist who would not take a more intelligent interest in Switzerland after having read it must know a good deal about the country; it is an excellent account of Switzerland which might be read with instruction even by persons who never look forward to seeing that country. The first paragraph of the first chapter deals with the *Urzeit*, or prehistoric period; the last chapter in the book sketches the history of the St. Gothard railway. The numerous excellent illustrations must add largely to the attractiveness and popularity of the series, which, however, the books well deserve on more substantial grounds.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts. No notice is taken of anonymous communications.*

[*The Editor urgently requests correspondents to keep their letters as short as possible. The pressure on his space is so great that it is impossible otherwise to insure the appearance even of communications containing interesting and novel facts.*]

On the Connection between Chemical Constitution and Physiological Action

IN his letter to NATURE last week (p. 594), Dr. Blake considers that I have not only misunderstood the scope of his experiments, but have been led into error on account of my having no definite idea of the meaning of the term chemical constitution, which he thinks I have evidently confounded with that of chemical composition.

In regard to the first of these points, I shall be very sorry if, by mishap, I have not rightly understood, or have failed to appreciate at their true value, Dr. Blake's experiments (most of which were published before I was born), for I regard him as a true pioneer in the field of pharmacology.

The scope of Dr. Blake's researches, as defined by himself in the Report of the British Association for the Advancement of Science for 1846, was "fully to establish the law of the analogous action of isomorphous substances."

I should no doubt have described Dr. Blake's researches more correctly had I used the word "isomorphous" instead of translating it into popular language, for my translation undoubtedly does not give the full meaning of the word; but my whole address was an attempt to make a difficult subject as popular as I could, and I thought that I had sufficiently acknowledged Dr. Blake's priority by observing that the present epoch of pharmacology might be dated from his researches, although it was those of Crum Brown and Fraser which fairly started pharmacological investigation in a new direction. Perhaps Dr. Blake will be inclined to regard my shortcomings in regard to him more leniently if he will read over my address again, for, if he does so, I think he will see that if on my part I have failed to give him due credit, he on his part has completely misunderstood the whole drift of my address, which was to show the importance of chemical constitution as distinguished from chemical composition. T. LAUDER BRUNTON

The Origin of Species

IT has already been pointed out by Mr. Evershed that the "physiological selection" of Dr. Romanes is identical with the theory outlined by me nearly two years ago in these pages (vol. xxxi. p. 4). As all the objections which have been raised apply equally to my theory, I may perhaps be allowed to give my answer to some of them; it will probably differ in some points from that promised by Dr. Romanes in the *Fortnightly*.

I quite agree with Mr. Wallace (in the *Fortnightly*) that it is only among the group of animals which have at least one common parent that the corresponding variations of the sexual organs which are required for physiological insularity would be likely to occur. But when he maintains that not more than two or three of such a group would reach maturity, and that therefore they would soon die out, he seems to me to forget that it is only on the average that the number would be so small. Many groups would be small, and would die out; exceptional families would be more numerous and more lucky; just as we can all point to human families where twelve or more children have reached maturity, though the average number of those who do so is under three in a family.

The survivors, more or less numerous, would generally not be scattered far from their common birthplace, so that their chance of finding one another would not be very small, especially if the sexual instinct was correspondingly modified, and this might well be the case from what we know of the connection between the psychical and physiological parts of the reproductive function. This presupposes some difference of smell, form, colour, &c., to enable an animal to distinguish those of its own family from the rest of the species, but this probably exists between any two animals.

They might thus be under no great disadvantage compared with the parent species, and they would have a counterbalancing advantage in the much greater adaptability to circumstances which a small group possesses. Any useful variation occurring in a large group, if not swamped by the effect of interbreeding with a large number of unimproved forms, must take many generations to modify the whole mass; while a similar useful variation occurring in one member of a small and physiologically isolated group could modify the whole group in a few generations. The existence of a six-fingered man in England would not appreciably modify the inhabitants in a thousand years, even if it was a slight advantage to have six fingers; while if a six-fingered man was introduced into an island with five other inhabitants, a fair proportion of the population would probably be six-fingered in three generations.

It is perhaps worth pointing out that the curious connection between colour and fertility, in which Mr. Wallace seeks for the explanation of the sterility of species, follows at once as a corollary from the doctrine of physiological selection. For, apart from any special modification of the sexual instinct, all animals seem to prefer to breed with those of their own colour, and hence *any* change of colour in the isolated family would be an advantage, and would indeed remove the one disadvantage under which such a family lies. So a change of colour, otherwise useless, would in such cases be preserved, and be found accompanying sterility with the parent species.

Another of Mr. Wallace's objections seems to me a strong argument in favour of my (and Dr. Romanes's) theory. He says that some animals, not only of different species but of different genera, can produce hybrids, and he instances the pheasant and black grouse. Now this is just what we ought to find on our theory, and ought not to find on any other. If either structural divergence or divergence in colour produces infertility, then the pheasant and the black grouse should be sterile, since they differ more, both in structure and colour, than many sterile pairs. But if species are produced sometimes by physiological isolation, but sometimes by other causes, such as geographical isolation, spontaneous distaste (not disability) for pairing, or even unaided natural selection, then those species which have been produced by aid of any of these latter processes will be fertile in spite of any ordinary amount of divergence, since nothing has occurred to render them otherwise; while those which have been formed by physiological isolation will be sterile even though they have hardly diverged at all. We cannot tell, without assuming what I am trying to prove, what form of isolation has been at work, except in the case of island species; but we can tell that there ought to be both very divergent fertile forms and slightly divergent non-fertile forms, and this is the case.

It has also been objected that the gradual increase of sterility, as we pass from different species to different genera and families, proves that divergence produces sterility. But it would exist on my theory; for if physiological isolation, more or less complete, occurs before each species is formed, it will have occurred at least twice between the members of two genera, and more often between those of two families. If B is separated from A by being nearly infertile, and C from B in the same way, C is likely to be still more infertile with A. But in some cases geographical or other isolation takes the place of physiological isolation, and then any number of successive divergences may occur without any accompanying infertility.

It has been said (I have lost the reference) that a certain amount of sterility has resulted in some cases from the divergence produced by artificial selection. It may be so. But on my theory, physiological isolation, the spontaneous occurrence of a fertility circumscribed by the boundary of common parentage, must be of very common occurrence, since it must have occurred not only once for each of most of the recognised species, but many more times when the resulting species has died out, and in some cases where the two species, though still existing, have not diverged in any way so as to suggest to observers that they are not one, (just as many island species do not differ perceptibly from those on the mainland). If spontaneous physiological isolation is so common, it would be certain to occur, at any rate in its commoner partial form, among the great variety of our domesticated animals, even if, as I believe, ordinary variation has no tendency to produce it.

Note upon the Habits of Testacella

BETWEEN four and five months ago I found eleven specimens of this slug upon a low wall surrounding the garden of a house

near the Oxford University Parks, and on the following day I captured eleven more in the same place. There had been exceptionally heavy rain, extending over some days, immediately previous to those on which I found the specimens, and it therefore seems probable that these animals are driven out of the earth when it becomes sodden with moisture. Thus it is possible to account for the capture of a very unusual number of specimens, for, as far as I can learn, the species has hitherto only been met with singly in this locality.

I have also ascertained what happens to the animals when the earth in which they are contained becomes hard and dry from the loss of water. A few of the twenty-two specimens were killed and hardened, and the remainder were put in a box containing earth, in which they buried themselves. In the press of other work the box was neglected, and remained untouched in my laboratory until to day, the earth having quickly dried into a hard cake. To-day I emptied the box, and fully expected to find the slugs dried up dead, but to my surprise I found twelve specimens alive, each encysted in a thin transparent capsule formed of the hardened mucous secretion of the animal's skin. The body was contracted, and oval in shape, but it had been so completely protected from evaporation that there was no noticeable reduction in bulk after these hottest months of the year, during which water had been entirely withheld. One or two specimens had died almost immediately after capture, and a few escaped, so that all those which bad been exposed to the heat and dryness in the box had become encysted, and survived in apparent bealth. EDWARD B. POULTON

Wykeham House, Oxford, October 19

Lepidoptera and Migration

THE subject of migration in connection with Lepidoptera is beginning to receive some attention at the hands of our best lepidopterologists. I am decidedly of opinion that the abundance or scarcity of many species of Lepidoptera is largely regulated by migrations from abroad. Last year our southern shores were visited by an abnormal number of rare *Sphingidæ*, but this year there have scarcely been any records of captures published concerning them. It would be interesting to know what are all the influences which cause these migrations, and if there is a periodicity to the phenomenal occurrences.

Birmingham, October 12 W. HARCOURT BATH

The Earthquake of October 16 in the Vosges, &c.

MAY I be allowed to call attention to the fact that Alsace lies on the direction of the great circle, "boundary of Tertiary formation of the United States," mentioned in my letter which appeared in your number of the 14th inst. (p. 570), and furthermore that Strasburg has been repeatedly shaken since 1355, the first date which I found recorded as having been marked by a shock. It is quite true that the interval between that shock and the next recorded (1556) was 201 years; but the greatest subsequent interval, that between the shocks of 1577 and 1655, was only of 78 years. This interval represents a multiple of 13, being $= 13 \times 6$. The interval of 13 is of frequent recurrence, as I purpose to show in a paper which I have about terminated on this question of intervals and periods of earthquakes.

Royal College of Science for Ireland, Stephen's Green, Dublin, October 23

RECENT ORNITHOLOGICAL WORKS

THE future student of British birds ought to have little difficulty in working out the distribution of species within the shores of Great Britain, so much excellent work having been done in the way of local lists during the last few years, and certainly one of the most useful will be the little work on "The Birds of Cumberland and Westmoreland," just issued by the Rev. H. A. Macpherson and Mr. W. Duckworth.[1] The situation of these two counties is interesting, especially to the student of migration, and the notes on the passage of water-birds and sea-birds are particularly good. The completeness of the information, and the concise and simple form in which it is conveyed, render this small book a model of what a faunistic work should be, and it forms a worthy accompaniment to the many excellent county lists of birds which have appeared in England during the last twenty years. It would be well if every expiring species in Great Britain had had its death-song as well sung as is the case with the Dotterell, by Mr. F. Nicholson, in the present work. While Protection Acts are spreading their ægis over many birds in the breeding season, so that the numbers are visibly increasing, and the enlightened care of a few landed proprietors aids the work of bird-preservation, there are still a certain number of species whose nesting days in this country are numbered, and which, like the Great Bustard and the Bittern, are doomed by the inexorable advance of civilisation to seek less over-crowded countries in which to breed. The (too probably final) breeding of the Dotterell in Cumberland is therefore appropriately described by Mr. Nicholson, who has himself taken the eggs in the county. An excellent account is likewise given of the breeding of the Pied Flycatchers.

We learn with some surprise that the White-headed Long-tailed Titmouse of Scandinavia, the true *Acredula caudata* (Linn.), "may be detected in Cumberland in mid-winter," when "the appearance of a flock of adults in their snow-white caps is refreshing to an insular observer.' We should like to see some of these Titmice, and may state that an example is a desideratum to the national collection, where we should be glad to receive a specimen. Our experience in France, where we have shot *all three* races of the *Acredula caudata*, is that it is impossible to detect the difference of the forms when in the open, though a difference in note led to our recognising *A. irbii*. We can only consider the true *A. caudata* to be a very occasional, though not impossible, migrant to our shores, and we by no means sympathise with the authors of the "Birds of Cumberland" in their suppression of the name of *Acredula rosea* for the British Long-tailed Titmouse, from a dislike to the "needless multiplication of species." As regards Great Britain the facts are perfectly plain. The resident *Acredula* is always recognisable, and the white-headed form is only a very occasional winter visitant, and however much they may interbreed in the Rhine Provinces or elsewhere on the Continent, there is nothing of the kind in England, where perfect differentiation exists; and therefore to say that our English Long-tailed Titmouse should be called *Acredula caudata* of Linnæus, is a mistake and nothing else, for that name belongs to the Swedish form. Those ornithologists who continue to do this suppress a most interesting fact in nature, viz. that the isolation of the British Islands from the rest of Europe has produced a well-marked modification in the colour of some of our birds, amounting in certain instances to a subspecific value. The same reasoning applies to the Coal Titmouse, where our authors state that "British specimens have *generally* olive backs, as contrasted with the slate-gray backs of typical German specimens, but intermediate forms occur." This is not our experience. In summer plumage, when the olive-brown tips and the feathers become shed, the back of the English Coal Titmouse is gray, and then it is difficult to tell it from a summer-plumaged *P. ater* from the Continent. But if two winter-killed birds are compared, the difference between the British and Continental specimens is very strongly marked, for the back in the latter remains gray, whereas in the British form it is olive-brown. Having been the first, as we believe, to detect this modification in the British form, we have, ever since we first gave it the name of *Parus britannicus*, assiduously collected a series of specimens in the British Museum, and we have never seen reason to modify our original opinion, nor have we yet seen the intermediate forms for which our authors vouch.

[1] "The Birds of Cumberland critically studied, including some Notes on the Birds of Westmoreland." By the Rev. H. A. Macpherson, M.A., and William Duckworth. (Carlisle, 1886.)

We must not conclude our notice of this interesting volume without calling attention to the excellent plate (by Keulemans) of the Dotterell in summer plumage, and of the useful coloured map, an indispensable adjunct for the proper comprehension of a well-written local avifauna such as the present.

We have recently received from America two publications of the highest value, dealing with the expeditions prosecuted under the auspices of the United States Government in the high north. In the *Bulletin* of the United States National Museum, Dr. Leonard Stejneger gives his "Results of Ornithological Explorations in the Commander Islands and Kamchatka." Dr. Stejneger has worked hard for several years at Palæarctic and Nearctic ornithology, and of the many important contributions from bis pen the present *Bulletin* is perhaps the most noteworthy. Although Kamchatka has been visited by several of the Russian naturalists, the published information respecting its ornithology has been meagre enough, if we except the labours of Dr. Dybowski, whose collections have been described by himself and Dr. Taczanowski. Dr. Stejneger divides his work into three parts: (1) a review of the species of birds collected or observed by himself on the Commander Islands and at Petropaulowski in Kamchatka; (2) a synopsis of the birds reported to inhabit Kamchatka; and (3) conclusions. One hundred and forty species were obtained by Dr. Stejneger himself, and of all of these he gives a full account, with synonymy and measurements. Naturally, the Auks, which abound in the Japanese and Kamchatkan seas, come in for a large share of attention, and Dr. Stejneger's description of these difficult species is very complete, especially as regards the shedding of the lamellæ of the bill, on which Dr. Bureau and Dr. Dybowski have had much to say in their writings. As these observations are accompanied by illustrations coloured on the spot by the author from freshly killed birds, there can be no doubt that they will be of inestimable value to the future student. Several new species are described, most of them, as might be expected, being extreme forms of Siberian birds. *Cuculus peninsulæ* represents *C. kelungensis* of Japan, *Dryobates purus* and *D. immaculatus* take the place of the Palæarctic Woodpeckers, *D. major* and *D. minor*; *Pica Kamchatica* that of the Magpie, *P. caudata*. The synonymy of the Redpolls is well treated, and a series of exhaustive measurements given. We can scarcely believe in the new race of the Scarlet Grosbeak, *Carpodacus erythrinus grebnitzkii*, seeing the variation which takes place in a series of *C. erythrinus* from other localities; nor can we distinguish the Kamchatkan race of the Yellow Wagtail, *Budytes flava leucostriatus*, which seems to us to be inseparable from *B. flava* of Europe, of which species it is an Eastern colony. If the differences pointed out by Dr. Stejneger hold good, it will solve an interesting problem in geographical distribution, because it will be much more simple to recognise three forms of *B. flava*: the ordinary one breeding in Europe and wintering in Africa; an Eastern form, *B. leucostriatus*, breeding in Eastern Siberia and wintering in the Malay Archipelago; and a central one, *B. beema*, breeding in Siberia and wintering in India. At present we have fully recognised the latter, whereas the European and East Siberian birds appear to be identical, though possessing well-defined breeding and wintering habitats, with the Central Siberian bird interposed as regards its breeding and winter range. Our synonymy of the Pied Wagtails in the "Catalogue of Birds" does not appear to be quite the same as Dr. Stejneger's, but the ground has now been cleared for Mr. Nicholson or the next bold man who makes the *Motacillidæ* a special study. The problems concerning the Wrens of the East which our author presents us with require careful consideration, and show that these representative forms cannot be disposed of in the off-hand way recently attempted by Mr. Dresser. Let no ornithologist neglect to study the "Conclusions" with which Dr. Stejneger finishes his work, as there are some admirable critical notes; and in conclusion we congratulate America on having gained from Europe such a thorough worker as the author of this volume shows himself to be. We have perused every page of his "Review" with interest, only regretting that our series of Kamchatkan birds is so poor in the British Museum that we have not been able to study, as we should have liked to do, with the specimens in our hands.

The bulky volume entitled a "Report of the International Polar Expedition to Point Barrow, Alaska" contains 24 pages of ornithology, by Dr. Murdoch, and many excellent notes on the birds are given. The chief interest centres round Ross's Gull, of which the Expedition "succeeded in obtaining a large series—more, in fact, than there were before in all the museums of the world put together." Coloured figures of the adult and young are given. So, slowly but surely, are the great desiderata of bird collections being rendered available for science. Only a few months ago this Gull was reckoned one of the greatest prizes to be obtained, and now we not only know the immature plumages, but something of its migrations and habits. Its previous rarity may be imagined from the fact that until the present year no specimen existed in the British Museum, where now, thanks to the liberality of Mr. Henry Seebohm, a fine adult bird is exhibited.

Our colleague, Mr. A. G. Butler, has varied his entomological pursuits by publishing a little work on British Birds' eggs,[1] the figures of which he has drawn himself; and he has shown himself as capable a draughtsman of eggs as he is admitted to be of Lepidoptera. The plates bear evidence of the difficulty which the author has experienced in mastering the shadows of the objects, as several plates are differently treated in this respect; and perhaps it would have been better if Mr. Butler had redrawn some of the earlier plates which did not satisfy him. The chromolithography, for which Messrs. Mintern are responsible, is certainly on the whole satisfactory, and may be found available for this kind of illustration, though we notice a tendency to heighten the colour, which in our opinion has hitherto proved an obstacle for the employment of the process as regards birds themselves. The figures of the eggs are, however, undoubtedly good, and no book yet published in this country shows in a better degree the variation in form and colour which eggs are subject to. In this respect Mr. Butler's little work will be useful to all oologists, and it can confidently be recommended to the young beginner as a hand-book. The letterpress is too short for a complete account of the nidifications of the birds, but contains a good deal of information in a narrow compass.

An "Oxford Tutor" in his little work, "A Year with the Birds," discourses pleasantly enough about his feathered favourites; and whether in the classic grounds of a college garden or in the mountains of Switzerland shows himself an observant student of Nature. We have read this book with considerable pleasure, and it has carried us back in memory to many such scenes as the author describes, though we have lacked his easy facility of recording his experiences. As he is interested in migration, we recommend his spending an autumn holiday on the milder parts of the south coast, where he may really meet with a "flock" of Blackbirds, and even of Robins and Hedge-sparrows. So keen an observer will find scope for his energy in the unravelling of some of the difficult problems which yet surround the study of some of our British species, and we may venture to point out to him one or two facts which have occurred to us during the perusal of his book. Thus, when he speaks of the Wheatear in Switzerland (p. 61) as "an English species,"

[1] "British Birds' Eggs: A Hand-book of British Oology." By A. G. Butler, F.L.S. 8vo. (London, 1886.)

we want to know whether it is the large or the small form which he met with. Again, on p. 73, when he talks of the "sheet of water or marshy ground which might attract the waders and sea-birds so commonly found near Oxford," is it not the east wind which drives the latter along the course of the Thames, rather than any peculiar attraction of the country near Oxford? The fact of the Cuckoo carrying her egg in her bill for deposit in the nest of her victims is now universally admitted; but what concerns ornithologists is the greater or less resemblance of the egg deposited by the female Cuckoo to the eggs of the foster-parents which she selects to bring up her young. The Spotted Flycatcher has undoubtedly a song (p. 83), but it is a poor affair, and is heard only, according to our experience, at daybreak. It is true that the Green Sandpiper (p. 86) has really only the legs greenish, but the reason of the perpetuity of the name to which our author objects, is because Linnæus called the species *ochropus*, and the name adopted by the older English writers was the *Green* Sandpiper, which has been handed down to the present generation, as is also the case with the Grey Wagtail. The author knows his "Dresser" and his "Harting," but he can learn something of the affinity of Robins and Redstarts (pp. 88, 101) from Mr. Seebohm in the British Museum "Catalogue" (vol. v.), or in his "History of British Birds." The little essay on the "Birds of Virgil" is most interesting, especially with regard to the *Alcyon*, which, we agree with the author and his authorities, was probably *not* our Kingfisher, though the presence of the latter on the sea-shore in some numbers is a fact at the season of the autumn migration. We offer these few remarks to the author as points of further study on which we should be glad to have the observations of a true naturalist, such as he evidently is.

The Rev. Gregory Smart has recently published a little book on the "Birds on the British List," which is a *critique* on the list issued by the British Ornithologists' Union, which he collates with the works of Mr. Dresser, Mr. Seebohm, and the fourth edition of "Yarrell." The book is disfigured by a slovenly style of writing, for which the printers' errors can scarcely account, and this is the greater pity, as the author's intentions are good, and he scores distinctly on several occasions when dissecting the evidence on which some birds are admitted to the British List while others are rejected; but the English in which he endeavours to record his conclusions is, to say the least of it, a little mixed. The author confesses to "having had but little experience," and it would therefore have been better to have restricted himself to the main object of his book, viz. the criticism of the evidence on which some species are retained or rejected in the works above alluded to. When he gets outside the boundary of his *critique*, he talks in some instances simple nonsense, as in his remarks on the Gold-vented Bulbul (p. 18). Mr. Dresser and Mr. Bidwell, in aiding and abetting Mr. Smart in his hap-hazard identification of his Bulbul's egg, could scarcely have expected the punishment of having their rash opinion published to the world. On p. 41 some more nonsense appears about *Anthus ludovicianus* and *A. campestris* being conspecific! The author would seem to be unaware that "Ungaru" is generally spoken of as "Hungary" by English writers, and that "Los Angelos Cala" is a locality which will puzzle many an "inexperienced" collector for whose benefit Mr. Smart professes to write. We would advise the author, before publishing another book, to get some friend to look over his manuscript for him, as a good deal of the difficulty of unravelling the meaning of his sentences would have been avoided by a simple attention to stops and commas, which is not too much to expect from a "late Scholar of Trinity College, Cambridge."

R. BOWDLER SHARPE

SOLAR PHYSICS[1]

MOST of our readers are aware that the sun, as constructed by Zöllner, was a white-hot, liquid body, that its spots were scoriaceous products of local cooling, and that its atmospheric circulation was closely modelled upon the terrestrial, with trades and anti-trades, an equatorial belt of calms, land- and sea-breezes, the last due to the contrast of temperature between the slag-islands constituting spot-nuclei, and the incandescent ocean in which they floated. On these lines M. Schulz has reared a solar edifice out of materials to a large extent new. Sixteen additional years of results in one of the most rapidly progressive branches of modern physical astronomy, give him an advantage over his predecessor, utilised to the utmost in modifying, extending, and generalising views of which he is the intrepid, though not blind, partisan. The upshot, we venture to assert, is to prove them wholly untenable. If M. Schulz's ingenious advocacy fail to recommend them, their inherent weakness must be great. Our readers shall judge for themselves of its success.

In the work before us it is undertaken to account for the whole array of solar phenomena, from the conservation, through long geological ages, of the solar activity, and its cyclical fluctuations, to the production of a pore or a facula. With this alluring prospect in view we are invited to regard the sun as a liquid globe composed of unknown substances, glowing at a temperature somewhere between 10,000° and 20,000° C. Although the heat rises towards the centre by a very low gradient, the inequality suffices to insure the distribution of the loss by radiation throughout the bulk of the globe, vertical convection-currents carrying down the cooler and heavier outer layers, and replacing them with hotter and more buoyant materials from the interior. Thus the danger is averted of the light-and-heat-giving career of our luminary being brought to a premature close by the untimely formation of a crust. The relative permanence of that career is further secured by the application to a liquid sun of Helmholtz's gravitational principle of the maintenance of solar heat.

The extensive atmosphere surrounding this molten mass is composed mainly of the unknown gas emitting Kirchhoff's "1474" line. This, in M. Schulz's opinion, is the primitive and simplest form of matter. Its atoms, many times lighter than those of hydrogen, are the fundamental units by the various aggregation of which the atoms of all other substances whatsoever are constructed. It plays, as we shall presently see, a very important part in the solar economy devised by our author. The solar supply of it is on a prodigious scale, since it fills, mixed with small percentages of hydrogen, helium, and metallic vapours, the vast spherical shell visible during total eclipses in the form of a "corona."

In the lowest strata of this gaseous envelope the photosphere hangs suspended at a height of a few thousand miles above the real surface of the sun. Its structure resembles that of our cirrus-clouds, only that metallic and incandescent condensing particles are substituted for aqueous frozen ones. The Fraunhofer absorption M. Schulz brings about by the customary machinery of the "reversing layer," regardless of the growing objections on the part of leading solar physicists to its exclusive employment in that capacity. Indeed the details of spectroscopic evidence scarcely receive from him the minute attention they deserve. Mr. Lockyer's researches on "lines widened in spots" give an example of the kind of work that has henceforth to be done on the solar spectrum. Summary explanations of its phenomena no longer suffice. Each one of its thousands of dusky rays has an individual story to tell, well worth the trouble of

[1] "Zur Sonnen-Physik." Von J. F. Hermann Schulz. Separatabdruck aus der *Gaea*, Bände xxi. und xxii., 1885-86. (Leipzig: W. Drugulin, 1886.)

inquiring into. Each has its own significance, and might be made the subject of a separate, and not unfruitful, study.

Prominences and spots are, by our author, connected together as cause and effect, but in the inverse order of their probable occurrence. There are strong grounds for the belief that the initial disturbance is that which occasions a spot, eruptive appearances ensuing consequentially. But, if M. Schulz's account of the matter were correct, no spot could arise without an introductory display of spontaneous and preliminary flames. Prominences, in his scheme, are composed exclusively of the green coronal gas "1474." It is true that in the spectroscope lines of hydrogen and helium are visible, but their meaning, we are told, has been misinterpreted. They take their origin, not from the body of the prominence, but from the glowing sheath with which the resistance of the solar atmosphere to its upspringing encompasses it. This surprising contention refutes itself. The implied resistance would, in a few seconds, shatter into inconspicuousness the rushing volumes evoking it. "Quiescent prominences," moreover, would on this theory be impossible; yet they are often plainly visible, for weeks together, in virtually unchanging forms; to say nothing of spectroscopic incompatibilities, too obvious to need dwelling upon.

The mechanical power consumed in the projection upwards of these bodies is derived from the expansive force of gas escaping from tremendous pressure. In dilating, however, it loses heat, and at such a rate that by the time the pressure upon it is reduced from ten million terrestrial atmospheres to one tenth of an atmosphere, its temperature has fallen from 12,000° to – 216° Centigrade. The ensuing condensation to the liquid and thence to the solid state brings about a fall of "1474 snow" upon the photosphere. When the shower is a light one, a "pore" is the consequence; when it is heavy and long-continued, the cold falling matter reaches the liquid sheet beneath, a group of "slag-islands" is formed from the chilly contact, and a spot becomes apparent to distant onlookers. The overlying photospheric clouds then arrange themselves, under the influence of atmospheric currents, into the characteristic funnel-shape of the penumbra, at the bottom of which lies the obscure solid nucleus, more or less veiled in dense absorbing vapours.

Improbability raised to an infinite degree becomes impossibility; and we may safely assert that that degree has here been reached. Criticism is silent in the presence of a supposition so fantastic as that of a substance presumably far less condensable than hydrogen existing frozen in the very depths of the thrice-heated furnace of the sun.

So much for prominences and spots: we now come to faculæ. They are regarded by M. Schulz as mere optical effects of irregular refraction in the agitated vicinity of spots. Yet the plainest ocular proof of their being real elevations above the general level of the photosphere is afforded by their not unfrequent visibility as projections from the smooth border of the limb, as well as by Dr. De la Rue's relief-pictures obtained by the stereoscopic combination of photographs.

The (not undisputed) higher equatorial temperature of the sun supplies M. Schulz, as it supplied Zöllner, with a "trade-wind" circulation, by means of which the retarded transport of spots remote from the equator are, with some difficulty, accounted for. Their slight displacements in latitude prescribe the mode of the sun's bodily circulation. A stupendous system of vorticose currents—set going by differences of specific gravity through surface-cooling—is disposed so as to impel such objects slowly towards the poles from about 15° of north and south latitude, while minor equatorial whirlpools give the observed opposite drift within those limits. But such an arrangement, even were it otherwise possible, would reverse Carrington's noted law of solar rotation, the angular rate of which would, under the supposed circumstances, *quicken* with advance poleward, while the maximum retardation would occur somewhere between ten and twenty degrees of latitude.

This rolling movement from within outward of the entire substance of the liquid solar globe, save a small dense nucleus, serves, however, a further purpose. It explains the spot-period.

The occurrence of spots, it must be remembered, depends primarily upon the escape of "1474" gas (which we may designate "coronium") from the interior. But how does it get there? M. Schulz's reply is to the following effect.

Coronium has a powerful affinity for a certain hypothetical solar constituent described as "spot-stuff." In middle and high latitudes a temperature as low perhaps as 9000° C. permits combination which accordingly takes place freely over a vast area. Huge masses of a compound of coronium with "spot-stuff" thus enter into the general circulation, and are gradually carried down to depths where a temperature enforcing dissociation is encountered, giving rise to the formation, under enormous pressure, of gigantic bubbles of pure coronal gas. By their variously-conditioned outbursts these finally occasion prominences and spots, which are more or less numerous according as the distribution of "spot-stuff" is more or less plentiful. Admitting some degree of permanence in its localisation, and assuming that the great vortices whirl once completely round in eleven years, the spot-cycle is established. The equatorial spot-and-prominence minimum finds its *rationale* in the higher temperature by which the occurrence of chemical association in any part of the separate equatorial vortices is prohibited.

We have endeavoured, while omitting details which it would be waste of time to dwell upon, to do no injustice to M. Schulz's ideas in our brief sketch of them. Yet it is difficult to treat them quite seriously; and we confess to a feeling of regret in seeing a writer of M. Schulz's ability and acquirements apply them to the elaboration of so baseless a series of hypotheses—baseless in this sense, that they rest upon a number of postulates which few will be disposed to allow. With sufficient liberality of assumption almost anything can be explained on any desired principles. But this is just the kind of supply which a prudent investigator is most chary of granting either to himself or others. For its misuse undermines the foundations of science, and involves in common discredit illusory theories and legitimate schemes of inductive reasoning.

It is not without cause that solar physicists have adopted what M Schulz calls the "gas-ball theory" of the solar constitution. A mainly liquid sun is for many reasons inadmissible. At a temperature of 10,000° C. and upwards, to begin with, no substance known to us upon the earth can exist otherwise than in a state of vapour. Hence the necessity for having recourse to unknown elements with preternaturally high boiling-points. But a theory of Nature built upon the unknown has, it must be admitted, no very secure basis. Further, the internal stores of heat of a liquid sun could not be made available at the surface. The heterogeneous materials presumably composing it would necessarily arrange themselves, in the order of their specific gravities, into a succession of shells growing in density towards the centre, which no possible convection-currents would have power to disturb. The result would be the formation of a crust, and—so far as we can see—the speedy and final cessation of the radiative function of our luminary.

Some of the points touched upon by M. Schulz are of great interest, and we cannot but feel grateful to him for emphasising them, however little we agree with his methods of elucidation. He shows, for instance, that an atmosphere of hydrogen could not, on any probable assumption as to temperature, extend much more than

3000 kilometres from the photosphere without producing an amount of pressure at its base which certainly does not exist. Yet the spectroscope tells us that incandescent hydrogen is actually present at a couple of hundred times that height. Nor can the anomaly be reconciled by supposing, with our author, the solar atmosphere to be chiefly composed of a very much lighter gas ("1474"), merely, as it were, adulterated with hydrogen. Even if we were satisfied to ascribe to "coronium" an almost impossible degree of elasticity, it would not avail to lift the mingled hydrogen one inch above its natural level. The law of diffusion does not abrogate the law of gravity. Each gaseous ingredient of a mixed atmosphere obeys its own law of equilibrium, as if it existed alone. It is true that the anticipated thinning out of oxygen at great heights in our own atmosphere has not been experimentally verified; but the incessant agitation of the air is believed to mask an effect which should otherwise be perceptible.

The action of a repulsive force, such as is visibly exerted on comets, has been invoked as a means of escape from this difficulty. The supposition has much to recommend it, and would remove a good deal of perplexity; it is, besides, countenanced by the authority of Dr Huggins. But the more tempting it appears, the more severely it should be tested previous to its admission, on other than a provisional footing, among the theories of science.

The slightness of resistance to motion in the solar neighbourhood is one among many indications of the extreme tenuity of matter there. Comets well-nigh graze the sun's surface without experiencing perceptible retardation; and millions of cubic miles of hydrogen sweep onwards or upwards at rates up to 250 miles a second, almost as if *in vacuo*. Since both the moving substance and the medium are incandescent, the varying viscosity of gases at high temperatures would claim attentive consideration in the matter, were it not that reliable data are unfortunately deficient.

The rotational peculiarity of the sun may, however, be said to dominate the problem of its constitution. Three classes of explanation are possible, and have found various degrees of favour. It may be produced by the fall of matter upon the photosphere, by the ascent of matter from beneath it, or by surface-currents. The last was the theory of Zöllner, and has been inherited from him by M. Schulz, but may be dismissed without hesitation as contradictory of known facts. M. Faye's hypothesis of vertical currents bringing up with them a smaller linear velocity is more plausible, but needs peremptory treatment to fit it to the required shape. It is remarkable that M. Belopolsky has lately deduced theoretically, on some not improbable assumptions, Spörer's empirical formula of the diminishing rate of the sun's rotation north and south from his equator (see NATURE, vol. xxxiv. p. 54). The coincidence is striking; but it must not mislead us. It is not enough that a cause be true; it must also be sufficient. Is there any likelihood of its being such in this case? We apprehend that the effects, even supposing them realised to the full, would be microscopic compared with those actually observed. If we take the mean density of the sun at double its superficial density (an outside admission), the maximum of gravity will occur below the surface, at a depth of one-sixth of the radius, and there the *theoretical* rotation-period comes out, by a rough calculation, about twenty-two days. But this period is not in reality complied with. The tremendous hindering power of friction intervenes. It occurs on paper only, and belongs even there but to a single stratum. The effects in superficial acceleration must be quite inconsiderable.

Acceleration from below failing, we turn to acceleration from above. And it has to be borne in mind that the mode of the sun's rotation is inferred from the movements of spots, and from them alone. But if spots be due, as generally supposed, to vaporous down-rushes, they must share in the augmented velocity brought by the materials forming them from regions of wider circumference; and this theoretical necessity is confirmed by the characteristic plunge forward attending the sudden development of these objects. If we assume further that the height of fall, consequently the added linear velocity, diminishes progressively with distance from the equator, the phenomena of spot-transport in longitude are satisfactorily accounted for. Just such a graduated elevation of the sources of spot-supply forms an integral part of Mr. Lockyer's "meteoric-ring theory" of sunspots, communicated to the Royal Society in May last (NATURE, vol. xxxiv. p. 251). The line thus struck out, however it may be modified by future experience, seems to lead, more naturally and easily than any other yet tried, to the solution of the problem of the sun's apparent rotation.

A. M. CLERKE

THE NEW OPTICAL GLASS

EVERYTHING that falls from the pen of Prof. Abbé of Jena relating to optical matters commands respect. His announcement therefore of the discovery of new kinds of glass specially adapted for the manufacture of lenses has been received with peculiar interest; and although details of information on various points are still wanting, enough has been published respecting the new optical glass to be worthy of more than passing notice.

All who have had anything to do with optical instrument-making know only too well the existence of the defect termed "irrationality of dispersion." When Hall and Dollond had independently shown that the chromatic dispersion of a crown glass lens might be corrected by combining it with a second lens of flint glass, a new impetus was given to optical research. The so-called "achromatic" lens in the hands of successive generations of opticians constituted the basis both of the modern microscope and of the modern telescope. But as greater and greater perfection in the construction of the "achromatic" lens was attained, it became apparent that perfect achromaticity was very far from being realised; for though two lenses might be found which should perfectly bring together two widely differing rays, such, for example, as the red of the line C of the spectrum and the blue of line G of the spectrum, it by no means followed that this pair of lenses would bring together to the same focus all other rays. On the contrary, owing to the "irrationality" of dispersion a "secondary spectrum" would always remain uncorrected

The relation between the chemical constitution of a medium and its action on waves of light of different periods is one of those matters about which we are still profoundly ignorant. We know that a prism of glass does not spread out the waves in proportion to their wave-length, or to the frequency of their periods. A simple case of irrationality is afforded in the fact that a green ray which when viewed through one prism may lie exactly half-way between C and G in the spectrum will not lie exactly half-way when viewed through a prism of a different kind of glass. All that a combination of two lenses can do is to achromatise for two rays of the spectrum: it may very nearly achromatise for the neighbouring rays, but strictly speaking it only achromatises for two. For ordinary optical purposes we seek to achromatise for the red and the blue, so reconciling the end regions of the visible spectrum. For photographic purposes we achromatise for green and violet (or even ultra-violet) rays, reconciling the end regions of the photographically active spectrum.

To Dr. Blair, whose observations were published in the *Transactions* of the Royal Society of Edinburgh for 1791, we owe the suggestion to achromatise for three rays by using compound lenses of three different media. Blair, indeed made a most extensive examination into the dispersive powers of various media, and in particular of

liquid media, which he proposed to use in his compound lenses; a fluid lens being formed in a cavity between two lenses of glass. He also suggested combinations of two or more fluid lenses. He found that in the spectrum of hydrochloric acid the green rays lay much nearer the violet than in the spectra of most metallic solutions; and he proposed to use the chlorides of antimony and of mercury in various proportions along with hydrochloric acid, or with sal-ammoniac, in order to obtain a fluid which, while having a different absolute dispersion from crown glass, should have its relative dispersion or relative distribution of the rays of different colours proportionately identical throughout the spectrum. Blair's object-glasses for telescopes, though regarded at the time as of singular merit, never came into use. The only recent serious attempt to revive a triple lens for approximating to a correction of the secondary spectrum by achromatising for three rays has been that of Prof. C. S. Hastings, of Yale, who has used three kinds of glass.

What Blair proposed to effect with his liquid combinations Prof. Abbé claims to have now achieved by his discovery of new kinds of optical glass. To Abbé we owe the remark that, in addition to the secondary chromatic aberration of our so-called achromatic lenses, there exists a second defect, termed by him the chromatic difference of the spherical aberrations. This term he uses to denote the fact that with the crown and flint glasses used by opticians, though the curves of the lenses be calculated to correct the spherical aberration, taking in each case the mean refractive power, there will be a slight residual spherical aberration for all rays not of mean refractive index; the lens being spherically under corrected for red rays and spherically over-corrected for blue.

Having realised so far back as 1880 that these defects were inherent in the use of such glass as opticians had at their disposal, Abbé determined to make a resolute attempt to discover new kinds of glass which should be free from these vices. The research involved no less a field of work than the examination of the optical properties of all known chemical substances which undergo vitreous fusion and solidify in non crystalline transparent masses, together with a detailed comparison of their physical and chemical properties. The work was begun so far back as January of the year 1881 by Prof. Abbé and his coadjutor, Dr. Schott, then of Witten in Westphalia, now of Jena. Dr. Schott undertook the chemical portion and the melting processes; Prof. Abbé and his assistant, Dr. Riedel, conducted the optical examinations of the products. At first only small quantities, from 20 to 60 grammes in weight, were melted at once; all kinds of chemical elements being tried with the view of ascertaining their influence on the refractive and dispersive powers. Not only were glasses of ordinary kinds having silicic acid for their chief constituent tried, but also glasses, resembling Faraday's famous "heavy-glass," made from boric acid and also phosphoric acid. So, by the end of 1881, a series of fundamental facts in chemical optics were gathered together for future use. The next point was to use these chemical researches as the basis for the production of real glass possessing the necessary qualities of hardness, colourlessness, and unalterability. To carry out this work, Dr. Schott moved to Jena early in 1882, and set up a special laboratory for scientific glass-making with proper blast-furnaces, and smelting-pots in which quantities of 10 kilogrammes could be melted at once. Until the end of the year 1883 this research-laboratory was occupied almost exclusively in working toward the solution of two practical problems. The first of these was the production of pairs of kinds of flint and crown glass, such that the dispersion in the various regions of the spectrum should be, for each pair, as nearly as possible proportional. The object of this was to permit of a higher degree of achromaticity than hitherto possible, by diminishing the secondary colouring effects inseparable from the irrationality of the ordinary silicate flint and crown glasses. The second problem was the production of a greater multiplicity in the gradations of optical glass in respect of the two chief optical constants, the index of refraction and the mean dispersion. Though this has not generally been regarded as an important need in optics, it was considered by Prof. Abbé and Dr. Schott as of quite equal importance to the first. For the silica glasses hitherto used constitute, according to their composition, a simple series, from the lightest crown to the densest flint, in which, with an increase in refractive index, there is practically always an increase in the mean dispersion. But there is no doubt that for many purposes of practical optical instrument-making, particularly in the designing of optical combinations for special purposes, it would be a great benefit for the optician to have at his command other kinds of glass in which the refraction and dispersion are not related in the way in which they are in the silica glasses; for example, a glass having great refraction and small dispersion. Hence the multiplication in the available kinds of optical glass opens out new possibilities of great practical moment. Pending the publication of these very valuable scientific investigations, only a very brief account can be given of the actual results. The first problem has been satisfactorily solved, with the result that achromatic lenses of a much more perfect kind than has ever been attainable are now in the market; and the second has also been successfully carried out, a whole series of new glasses of graduated properties having been introduced into the optical trade.

Down to the autumn of 1883 the matter was one of systematic scientific research; but at that date, encouraged by the substantial fruit borne by the investigations, a further step was taken. In conjunction with the brothers Dr. Carl Zeiss and Dr. Rod. Zeiss, of Jena, whose names are household words to every microscopist, a commercial enterprise was set on foot for establishing a new glass-foundry. This establishment, which, under the style of Schott and Company, has been at work since the autumn of 1884, produces glass of all kinds, old and new, on a large scale. The first application of the new glass to the microscope comes naturally from the famous firm of Zeiss. To his new microscope lenses Prof. Abbé gives the distinctive name of *apochromatic objectives*. He claims for them great superiority in the finer qualities of definition, the new dry apochromatic lens giving an image equal to that of an ordinary achromatic water-immersion objective. He also claims that the more perfect corrections permit equal magnification to be obtained by using a longer-focus objective with an eye-piece of higher power than hitherto has been usual, thus obviating some of the difficulties of very short-focus objectives. Moreover the foci for visible and for photographic purposes are identical. Special compensating eye-pieces have been also devised for use with the new apochromatic objectives.

Whether these new appliances are found to fulfil under the test of experience all that their inventor claims for them remains yet to be seen; but it cannot be doubted that a great step has been taken. It ought also to be recorded to the credit of all concerned that no attempt is being made to secure to one firm a monopoly of the new materials, but that the new optical glass is offered to the optical trade without any restriction or patent to stand in the way of further development. Nor less honourable or significant is it that the researches of the "Glass-technical Laboratory" of Jena should have been supported by a very liberal and several times repeated subvention from the Prussian Government. Such a result arising from the endowment of research makes ample answer to the easily-uttered assertion that such endowments, if given, would be wasted on useless fancies and trifling schemes. We sincerely congratulate Prof. Abbé and Dr. Schott on the completion of their most meritorious labours.

THE GERMAN NAVAL OBSERVATORY[1]

IT will be remembered by our readers that in the spring of the present year a review of the sixth yearly Report of the German Naval Observatory at Hamburg was given (NATURE, vol. xxxiii. p. 411), in which the objects and the general system of working in the several departments, as well as some special papers on subjects connected with the Observatory, were noticed.

In this, the seventh yearly Report, there is the same evidence of the progress of useful work in all departments described in the first of the four papers which it contains, but not requiring special remark. In Paper No. 2, however, there is a detailed account of the building in which this work is carried on, and a general description of the instruments employed, which can hardly fail to be of interest even to those who may have personally visited the Observatory.

The traveller approaching the docks of Hamburg by the Elbe, will see a square sandstone building in the Renaissance style situated on an eminence which rises abruptly 100 feet above the river, between Altona and Hamburg. This is the Naval Observatory, in an excellent position for observations, and commanding an extensive view of surrounding objects for many miles, close to the shipping for the welfare of which it was chiefly established, and as it were inviting the commanders to come and partake of the advantages held out to them. The main building—which in plan forms a hollow square, and consists of a basement, ground floor, and two stories above, with ample internal galleries and staircases for communication with the various rooms—was commenced in 1879 and completed in October 1881, a Naval Exhibition in the lower rooms having been opened in the previous month by the Emperor of Germany in person.

Over the principal entrance, which faces towards the south-west, are three busts of well-known scientific worthies, that of Dove being in the middle, with Maury and Rümker right and left. The square inside the building is roofed with glass, giving protection to the galleries and the Combe apparatus which occupies the floor, whilst it proves but a small obstruction to the light.

A view from the north-west side of the building will be found on Plate 1, and on Plate 2 a plan showing the general disposition of the adjoining structures.

Preceded by some historical references to the site now occupied by the Observatory—where fortifications formerly existed—in pp. 5-12 will be found a description of the uses to which the various rooms are devoted, with references to the twenty-nine excellent plates, showing their size, and the mounting of the various instruments in them, both in elevation and plan. At each angle of the building there is a low square tower. On the western of these the anemometers and wind-vane are mounted, with electrical communications to the registering apparatus. In the south tower is the apparatus for proving sextants, for which the known angles between well-defined distant objects are used, it being a rare occurrence for the latter to be obscured by fogs. A transit instrument occupies the eastern tower, and an alt-azimuth instrument the northern.

From pp. 12-26 detailed accounts are given of the principal normal and self-registering instruments, the laboratory, the compass observatory, and the museum with its contents. Amongst the special apparatus a registering rain-gauge is described at p. 27, with an illustration; this, with the sliding-weight barograph described on p. 29, was designed by Dr. A. Sprung.

The magnetic pavilion in the garden is chiefly devoted to experimental determinations of the induction-coefficients for various kinds of iron, and instruction to students in magnetism.

[1] "Aus dem Archiv der Deutschen Seewarte." VII. Jahrgang, 1884. Herausgegeben von der Direcktion der Seewarte. (Hamburg, 1886.)

Some remarks on the uses of the Combe apparatus, founded on information of a later date than that of the present Report, may possibly be of interest. A doubt has already been expressed (NATURE, vol. xxxiii. p. 411) as to the value of the effects produced on chronometers by machinery for simulating the rolling and pitching motion of a ship at sea. This doubt has been confirmed by experience, and some additions have been made to the apparatus by which the effects of shaking such as might be caused by the racing of the engines on board ship or the blow of a heavy sea are introduced. These effects of shaking are clearly shown in the rates of the chronometers tried.

As the Combe apparatus can be rapidly revolved by means of a gas engine, its uses have been extended to the trial of anemometers and the measurement of wind-pressure, the arrangements for which may be seen on Plate 18, and a description of the same on pp. 12-15. It is reported that the results obtained are satisfactory with the exception of minor effects on the anemometers caused by draughts passing through the arched openings to the adjoining corridor, but this is in a fair way to be accurately accounted for.

In Paper No. 3, the course of instruction used by students at the Observatory on the mathematical treatment of the deviation of the compass, with examples, is shown in detail. A certain knowledge of mathematics and mechanics is required of the students preliminary to this instruction, but they have the assistance of Dr. Neumayer's deviation model (NATURE, vol. xxxiii. p. 587) for experimental illustration.

The formulæ used are, with one exception, those of the Admiralty Manual for Deviations of the Compass, published in London in 1869.

The exception will be found on pp. 29 and 30, where it may be seen that a new term is introduced into each of the equations representing the fore-and-aft and transverse magnetic forces of an iron ship. The object is to give a mathematical expression for the temporary changes which are produced in an iron ship's magnetism when her course lies in a given direction for a few days, or even hours, under certain conditions—the change only becoming apparent on alteration of the course. The amount of change experienced depends upon the quality of the ship's iron, the position of the compass, the length of time she is kept on the given course, the degree of shaking she is subjected to during that time, and is proportional to the earth's magnetic force at her mean geographical position. The question is more fully discussed in the *Archiv der Deutschen Seewarte* for 1879, No. 4, where some values of the changes denoted by the constants V and V' for certain ships are tabulated, but these values are dependent on so many contingencies, that nothing but carefully-conducted observations systematically made for each ship can give exact results. It may be remarked, however, that from results of the kind just described properly analysed, much useful information might be deduced and furnished to iron vessels proceeding on a voyage, as to the probable changes in their magnetism under various conditions.

The general rule at present is to depend entirely on observations of the deviations of the compass and their registration for future guidance when observations cannot be obtained. There is much to be said in favour of this rule, but there is also much to be hoped for from the more scientific treatment. It may be added that as similar results are often obtained in vessels of like types of construction, the analysis of observations from many vessels is much to be desired for the guidance of commanders of vessels starting on their first voyage, possibly, in weather when objects on land or in the sky are invisible.

In the fourth and concluding paper an account is given of the observations made by Dr. Richard Neuhauss during a voyage from Germany to Australia by the Suez Canal

route, returning by New Zealand, Samoa, the Sandwich Islands, San Francisco, and New York. The observations relate principally to barometrical heights, temperature of air and sea, moisture of the atmosphere, and twilight phenomena, including zodiacal light, whilst passing through the Red Sea and tropical portions of the Indian and Pacific Oceans.

Although in previous yearly Reports Dr. Neumayer has published much information respecting the internal working, aims, and results of the Observatory he so ably directs, it is only from the perusal of this seventh Report that a full idea of the pains which Germany has taken on behalf of her sea-going population, in building and equipping at considerable expense the noble Naval Observatory at Hamburg, can be obtained. It should also be remembered that there are several minor affiliated institutions in Germany of like intent.

THE INSTITUTION OF MECHANICAL ENGINEERS

AT the recent meeting of the Institution of Mechanical Engineers, held in Leeds under the presidency of Mr. Jeremiah Head, a paper was read "On Triple-Expansion Marine Engines," by the late Mr. Robert Wyllie of Hartlepool. During the last few years the high-pressure triple-expansion engine has proved the successful rival of the double-expansion compound, and the object of the paper was to bring forward the results of recent experience with this new type of engine, and to consider briefly the various points which have a direct bearing on its efficiency, as well as the most suitable design for marine purposes. The general conditions of efficiency were stated to depend on the approximate equality in the range of temperature in each cylinder, in the initial stress on each crank, and in the indicated horse-power of each engine. As complementary to these are steam-jacketed cylinders and other matters which are first treated of. As regards steam-jackets, when in triple-expansion engines attention is paid to the equal division of the total range of temperature amongst the cylinders in which the successive stages of expansion take place, the benefits arising from the use of steam-jackets are naturally not so great as in single-cylinder engines with a high rate of expansion; but however carefully the triple engine may be designed, the jacketing of at least the intermediate and low-pressure cylinders is essential to maximum efficiency. The ratio of the cylinder capacities depends on the pressure of the steam and type of engine, the high-pressure cylinder being larger in proportion where large range of power and economy of fuel is not so important, as in war-ships as compared with cargo steamers. To obtain even approximate equality in powers, temperatures, and stresses requires the greatest care in designing the steam-passages throughout the engine, so that the velocities of the steam at the various points and the degrees of cut-off by the valves may be carefully proportioned. Too much care cannot be taken in the design of the steam-ports and exhaust-passages of the low-pressure cylinder. The ports should be as small as possible to reduce the clearance to a minimum, and the speed of the entering steam should not be so high as to cause excessive frictional resistance, nor that of the exhaust so high as to augment the back-pressure, and consequently the greatest efficiency is obtained when the revolutions and indicated horse-power are not required to vary to any great extent. Contracted or indirect exhaust-passages in the high-pressure and intermediate cylinders have the effect of causing a larger difference between the back-pressure on one piston and the initial pressure on the next, thus diminishing the efficiency of the steam. The cut-off necessary for the highest efficiency is governed to a great extent by the speed of the entering steam and the nature of the passages. In the intermediate and low-pressure cylinders, too high a velocity of the entering steam will produce excessive frictional resistance, causing a drop in the expansion-curve, as well as unduly high receiver-pressure, thus disturbing the equality of temperatures and of initial stresses. Some diversity of opinion has existed as to the order of sequence for the three cranks. The author considered the best sequence to be the high-pressure leading, low-pressure following, and intermediate last. As regards the number of cranks, the best design is to have two cylinders on each crank for a two crank engine on the triple-expansion system, as it is then possible to get an approximately equal initial stress on each crank, the arrangement necessitating one of the three stages of expansion taking place in two cylinders instead of in one. A marine engine should be so designed that any working part can be easily examined or removed, the arrangement of cylinders on three cranks fulfilling the required conditions more nearly than any other design. The requirements of a good valve-gear are, that it shall give at both ends of the cylinder an equal distribution of steam at all grades of expansion, with a minimum of working parts and no undue strains. The four principal methods are: by the single eccentric, by the double eccentric, by taking the motion from the connecting-rod, and by a compound motion derived from both the piston-rod and the connecting-rod; all have their advantages and defects, and vary considerably in complexity and multiplicity of parts. A comparison of practical results with compound- and triple-expansion engines is in favour of the latter, as regards dead-weight carried, speed, indicated horse-power, and coal-consumption, the latter being so low as 1·41 lbs. per h.p. per hour, proving this class of engine to be most efficient. The paper concluded with a reference to artificial draught for boilers, in the special arrangement described the air being heated both inside and outside the uptake, balanced fire doors being applied, which on being opened shut off automatically the hot air supplied by the fan both above and below the fire-bars.

An important discussion followed the reading of the paper. Mr. Wm. Parker, of Lloyd's, looked upon the triple-expansion engine as the engine of the future. Profs. Kennedy and Smith drew attention to the high initial pressures employed in the triple engine, 150 lbs. per square inch as compared with 75 lbs. per square inch in the compound engines being the cause of their higher efficiency; and other speakers having drawn attention to special features in the designs, the further discussion of the paper was put off to the spring meeting of the Institute.

Afterwards the President, by request, declared the Leeds Engineering School of the Yorkshire College open, and spoke in hopeful terms of the useful work it had doubtless before it.

NOTES

WE regret to have to announce the death last week of Dr. Guthrie, Professor of Physics at the Normal School of Science.

WE understand that the Jardin des Plantes has acquired for its botanical collections the herbarium of Lamarck. We do not know under what circumstances this had travelled so far from France. But until recently it was the property of Dr. Roeper, Professor of Botany in the University of Rostock. He incorporated it with his own herbarium, and the whole was purchased at his death by the University for 21,000 marks (1050*l.*). Lamarck's plants have however been separated, and as we understand purchased by the French Government.

THE front and sides of the new building for the galleries of natural history in the Jardin des Plantes are now nearly complete. But it will be two years or nearly so before the interior and the fittings can be finished. The collections will then be moved into the new portion, and the present galleries rebuilt to form the back of the square. The hollow interior will be covered

with a glass roof, and will thus be available for the reception of large objects. In the new front the mammals will occupy the ground-floor and the birds the gallery above.

The French National Museum has received a valuable collection of mammals obtained during M. de Brazza's recent expedition in the Congo district. In it are examples of two new and well-marked species of monkeys of the genus *Colobus*, and specimens of a very fine new *Cercopithecus*, allied to *C. diana*, which M. Milne-Edwards has named *C. brazzæ*. There are also examples of several other mammals of considerable interest. Looking at these discoveries and others recently made in Somaliland, it is evident that the mammal-fauna of Africa is by no means yet exhausted.

The experiment has been tried at the Finsbury Technical College of giving free Saturday evening popular lectures and of afterwards allowing the visitors to see over the laboratories and workshops. The lectures were given by the Professors of the College on the following dates:—October 2, Prof. S. P. Thompson, D.Sc., on "Waves of Light"; October 9, Prof. J. Perry, F.R.S., on "Spinning Tops"; October 16, Prof. R. Meldola, F.R.S., on "Coal, and what we get out of it." The concluding lecture was given on Saturday last, October 23, by Prof. Thompson, on "Magnets and Electro-magnets," the Lord Mayor taking the chair for the occasion. The numbers of visitors filling the lecture theatres on these occasions show that the movement has been appreciated by the public.

Prof. Frederick McCoy, of the University of Melbourne, has been appointed a Companion of the Order of St. Michael and St. George.

We are glad to hear that the completed volume of the "Zoological Record" may be expected before the end of the year; the reports on mammals, birds, and reptiles were issued to subscribers six weeks ago, and those on insects are now ready.

Two new botanical journals have recently made their appearance in Italy, named—according to the fashion of *Linnæa*, *Grevillea*, and *Hedwigia*—after the two distinguished botanists De Notaris and Malpighi. Three quarterly numbers have now been published of *Notarisia*, a journal devoted to the interests of phycology, issuing from Venice, and edited by Sigg. De Toni and Levi. A very useful feature in this publication is the list, in each number, of the phycological literature, and the descriptions of all new species published during the quarter. *Malpighia*, of which the first monthly number is issued, edited by Sigg. Borzi, Penzig, and Pirotta, and published at Messina, is of a more general character. Besides reviews, short notices, and a bibliography, it contains articles "On the Atomic Weights of Living Things," by L. Errera; "On the Structure of the Nectaries of *Erythronium dens canis*," by S. Calloni; "On Soredial Sporidia of *Amphiloma murorum*," by A. Borzi; and "Researches on a Species of *Aspergillus*," by F. Morini.

A curious custom of the natives of Java in the neighbourhood of the Bromo volcano is recorded in the *Straits Times* of Singapore. It is said that whenever an eruption takes place, the natives, as soon as the fire (the molten lava no doubt is meant) comes down the mountain, kindle at it the wood they use as fuel for cooking. They keep in the fire thus made for years, and whenever it goes out through neglect, or for any other reason, they never kindle it anew from matches, but they get a light from their nearest neighbours, whose fire was originally obtained from the volcano. The fires in use up to the late outburst in the native cooking-places were all obtained from the Bromo eruption of 1832.

The issue for last year (No. 16) of the *Journal* of the Straits Branch of the Royal Asiatic Society does not contain much of specially scientific interest, although there are interesting papers on various subjects connected with the Malay Peninsula. Mr. Perham translates a very old and popular Dyak myth, and Mr. Hale, Inspector of Mines at Kinta in Perak, writes on mines and miners there. Some of the customs described are very curious. The Malay miner, the writer says, has peculiar ideas about tin and its properties. He believes that it is under the protection and command of certain spirits whom he considers it necessary to propitiate. He thinks the tin itself is alive and has many of the properties of living matter, that of its own volition it can move from place to place, that it can reproduce itself, and that it has special likes and dislikes towards certain persons and things. Hence he thinks it advisable to treat tin-ore with a certain amount of respect, to consult its convenience, and to conduct the business of mining in such a way that the tin-ore may, as it were, be obtained without its own knowledge. There is also an interesting vocabulary of the language of the Sulu archipelago, which is said to be a variety of the Bisaya of the Philippines.

On Saturday M. Miclucho Maclay opened at St. Petersburg his small exhibition of ethnological objects from New Guinea and the Malay Archipelago in one of the halls of the Academy of Sciences, and delivered a lecture on Russian colonisation in New Guinea to the assembled visitors.

The International Congress of Hydrology and Climatology met at Biarritz in the first week of October under the presidency of M. Durand Fardel. The number of members reached from 800 to 900.

The National Fish Culture Association are constructing a new hatchery, and making other improvements at their establishment at Delaford Park, towards the expense of which they have received 200 guineas from the Fishmongers' Company. Donations have also been received from the Duke of Bedford, the Marquess of Exeter, Sir Albert K. Rollit, Mr. Mann, and others, towards the same object.

We have received the report of the West Kent Natural History, Microscopical, and Photographic Society for the past year. The Presidential Address by the Rev. Andrew Johnson dealt mainly with the progress made in one branch of mycological science, the *Agaricini*, during the last twenty years, starting from the publication of Berkeley's "Outlines of British Fungology," local Societies such as this are, we think, best judged by the local work they do, not by the lecturers they may succeed in getting to address them. Good-natured scientific men of eminence who will consent to address local Societies can be obtained without very great difficulty if approached in the proper way, but to have good local papers a Society must have local members capable of good steady scientific work. In this respect the West Kent Society is not wanting, for the principal paper in this report is one by Mr. Spurrell, entitled "A Sketch of the History of Rivers and Denudation of West Kent," which is an exhaustive account of the geology of the neighbourhood, which may be presumed to be specially within the scope of the Society's work. It occupies about fifty pages, and has a considerable number of plates and illustrations.

From the Report for 1885 of the Australian Museum, Sydney, we learn that the Museum is open to the public from 10 until 5 o'clock (or in summer till 6 o'clock) on week-days, on Sundays from 2 o'clock to 5. The largest attendance on any one day was 1686. The greatest Sunday attendance was 1230. The average daily number of visitors throughout the year was 264 on week-days and 844 on Sundays. The total for the year was 126,512. The collections are still being increased, by means of purchases, exchanges, and donations; also by collecting and dredging expeditions. A list of these additions, under separate heads,

is given in appendixes. Among these may be specially mentioned presentations in exchange from the Royal Museum at Florence; about 2000 Indian fishes from Dr. Day; three whales, caught on the coast of New South Wales; and sundry specimens of ethnology from the South Sea Islands, casts of natives of Micronesia and Polynesia, from Dr. Finsch, &c. A compass and collecting-jar belonging to Capt. Cook, purchased by the Agent-General and presented by the Colonial Secretary, are not without interest. Great alterations and improvements are still in progress, by the erection of additional glass cases. It is contemplated shortly to re fit the old wing of the Museum with cases suitable for the mineralogical collections, which will then be exclusively placed there. Rooms have been fitted up for the osteological collections, which are now being removed thither from other parts of the building. The want of sufficient space in the present building for the constantly-increasing number of exhibits is still felt as a serious drawback to the usefulness of the Institution. The trustees are preparing a proposal for consideration by the Government, which, if adopted, will provide a useful and permanent extension now urgently required, at a comparatively small cost. Catalogues, not only of the various collections in the Museum, but also of all branches of Australian zoology, are still in course of preparation. The following new publications have been issued during the past year:—"Catalogue of Hydroid Zoophytes"; "Catalogue of Echinodermata, Part I. Echini"; "Catalogue of Minerals." Catalogues of Sponges and Medusæ are in the printer's hands; and it is hoped that, by the liberality of the Government, the continuation of "Scott's Lepidoptera" will soon be commenced.

A TELEGRAM from Srinagar, Cashmere, states that a severe and prolonged earthquake was felt there early on the morning of the 20th inst. The damage caused is not yet known. Sharp shocks of earthquake were felt early on the morning of the 22nd at Charleston, Savannah, Augusta, Columbia, Orangeburg, Wilmington, North Carolina, and several other places. The first shock of earthquake was felt at 5 o'clock in the morning, and some sharp shocks followed at 3 o'clock in the afternoon. No damage is reported to have been done. A shock was felt at Louisville in the afternoon. The shocks of earthquake felt in the evening were more severe than any that have been experienced since the great earthquake of August 31. The shock was severely felt at Summerville, where some persons were thrown down and slightly injured. Several geysers have appeared in the neighbourhood of that town.

A CORRESPONDENT of the *Times* (October 21) who appears to have made a special study of Burmah, referring to the ethnology of that country, says that tradition points to three main streams of colonisation into Burmah. The northern sea-board, now known as Aracan, is said to have received its earliest population and polity from the Buddhist kingdoms of Bengal. The southern sea-board, or Pegu, with Rangoon as its modern capital, is supposed to owe its civilisation to settlers who crossed the sea from the Madras coast. The ancient kings of the inner country, which we call Upper Burmah, also claimed an Indian affinity. But, as a matter of fact, they and their people poured across the mountains and down the river valleys from the confines of China and Mongolia. These three prehistoric divisions have left their mark on the political geography of Burmah at the present day. Each of them has in turn advanced upon and crushed its neighbours, while the whole has been from time to time submerged by fresh avalanches of wild races from the north and east.

NEXT March the railway from Oran to Tunis *viâ* Algiers and Constantine, will be completed, and will be between 800 and 900 miles long.

WE have received from Messrs. Goolden and Trotter a small illustrated pamphlet descriptive of their dynamos, which appear to be well-designed modifications of the familiar Gramme machine, lamps, and other appliances for electric light. The pamphlet is also a price-list, and though with the latter feature we have nothing to do, we may remark on a curious and scientific innovation in stating the price of dynamos in a mathematical relation to their output, being, in fact, stated as 8*l*. 10*s*. per 1000 watts plus a constant of 25*l*. Trotter's dioptric shades, which are another speciality of this house, are an example of a great improvement effected in a common manufacture by the application of good geometrical and optical principles, and we have pleasure in noticing them on this account.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus* ♂) from India, presented by Mrs. H. Reader; two Green Monkeys (*Cercopithecus callitrichus* ♂ ♀) from West Africa, presented respectively by Mr. J. W. Bacon and Mr. G. D. W. Ingham; a Canadian Beaver (*Castor canadensis* ♀) from Canada, presented by the Earl of Carnarvon; a Crested Porcupine (*Hystrix cristata* ♀) from Ceylon, presented by Mrs. E. Dunn; a Grey Seal (*Halichœrus grypus* ♀) from the North Atlantic, presented by Mr. H. Overton; a Quail (*Coturnix communis*), an Asiatic Quail (*Perdicula asiatica*) from India, presented by Dr. A. Günther, F.Z.S.; a Pig-tailed Monkey (*Macacus nemestrinus* ♂) from Java, six Mute Swans (*Cygnus olor*), a Cormorant (*Phalacrocorax carbo*), British, deposited; a Scarlet Ibis (*Eudocimus ruber*), a Common Boa (*Boa constrictor*) from South America, received in exchange; a Vulpine Phalanger (*Phalangista vulpina*), born in the Gardens.

OUR ASTRONOMICAL COLUMN

THE DISTRIBUTION OF THE STARS IN SCHÖNFELD'S "DURCHMUSTERUNG."—The extension of Argelander's survey of the heavens from the North Pole to 2° of south declination undertaken by his successor, Prof. Schönfeld, has recently been published, and contains the places of stars down to mag. 10, situated between 2° and 23° of south declination. Prof. Seeliger, in a paper entitled "Ueber die Vertheilung der Sterne auf der Südlichen Halbkugel nach Schönfeld's 'Durchmusterung,'" published in the *Proceedings* of the Mathematico-Physical Section of the Bavarian Academy of Sciences, has discussed the question of the distribution of these stars. He divides the stars into eight classes. Class I. contains those of mag. 1–6·5, Class II. those of mag. 6·6 7·0, and so on down to Class VIII., which contains stars of mag. 9·6–10·0. Prof. Seeliger then gives the number of stars in each class arranged in zones embracing 1° in declination, and grouped by intervals of 40m. in R.A. The totals for each class are: Class I. 1265, Class II. 1276, Class III. 1828, Class IV. 3516, Class V. 7601, Class VI. 18,633, Class VII. 55,565, and Class VIII. 43,896. The total number of stars thus counted is 133,580, and adding to this 79 objects which are classified as nebulæ or variables, there results the grand total 133,659. This total agrees with the summation of the numbers given by Prof. Schönfeld. Comparing the results contained in this paper with those in a similar paper on the stars in Argelander's "Durchmusterung," Prof. Seeliger finds that, as far as Schönfeld's work can be considered typical of the southern hemisphere as a whole (it must be remembered, however, that it only embraces one-third thereof), the influence of the Milky Way on stellar distribution, at least for stars down to mag. 8, appears to be less marked for the southern than for the northern hemisphere. With regard to the question as to which hemisphere is the richer in stars, it appears that there is no decided difference shown by the two surveys under consideration. Reducing Argelander's numbers so as to make them comparable with Schönfeld's, and taking stars down to mag. 9 inclusive, we have for the former the total 34,324, and for the latter 34,119, a difference which may reasonably be attributed to accidental circumstances.

ASTRONOMICAL PHENOMENA FOR THE WEEK 1886 OCTOBER 31—NOVEMBER 6

(FOR the reckoning of time the civil day, commencing at Greenwich mean midnight, counting the hours on to 24, is here employed.)

At Greenwich on October 31

Sun rises, 6h. 54m. ; souths, 11h. 43m. 44·1s. ; sets, 16h. 34m. ; decl. on meridian, 14° 11′ S. : Sidereal Time at Sunset, 19h. 13m.

Moon (at First Quarter on November 3) rises, 11h. 9m. ; souths, 15h. 35m. ; sets, 20h. 0m. ; decl. on meridian, 18° 56′ S.

Planet	Rises	Souths	Sets	Decl. on meridian
	h. m.	h. m.	h. m.	° ′
Mercury	8 56	13 0	17 4	21 42 S.
Venus	6 3	11 14	16 25	10 17 S.
Mars	10 44	14 32	18 20	24 5 S.
Jupiter	5 14	10 41	16 8	7 11 S.
Saturn	20 57*	4 59	13 1	21 18 N.

* Indicates that the rising is that of the preceding evening.

Occultations of Stars by the Moon (visible at Greenwich)

GEOGRAPHICAL NOTES

The October number of *Petermann's Mitteilungen* begins with an article, with numerous maps, on the canal between the German Ocean and the Baltic, by Herr Beseke. It describes in detail the numerous early projects—sixteen in all—for the construction of a canal across the isthmus, and then the origin and progress of the project of a canal called *par excellence* the Imperial Canal. The last section of the paper deals with the influence of the canal on navigation, and its military and commercial advantages. But the most important paper in the number, and one of the most interesting that we have read for some time, is one on the changes wrought by man in the flora of Chili, by Dr. R. A. Philippi. Only the first part is published in the present number. These changes are enormous. The traveller in Chili, says the writer, as he passes by the fields and gardens, can scarcely believe that he is in America, not in Europe, so greatly has the native vegetation disappeared. The trees and plants of Europe, and only these (with the exception of the native potato), are found everywhere near habitations. The original native flora has to be sought with care and system, and is to be found only miles away from cultivation and the abodes of men. In fact, the native vegetation is destroyed by that of Europe as effectually as the native himself disappears before the white man. Dr. Philippi treats first of timber-trees introduced from Europe or North America, then of fruit-trees, then cereals, roots which serve for fodder, industrial plants such as the hop, sugar-cane, &c., vegetables, and finally weeds. The last class owes its origin to ordinary cultivated plants running wild, and to seeds which have found their way to Chili in other seed. Herr Wichmann concludes with a short sketch of the Galla States to the south of Abyssinia, with an elaborate map showing the routes of Cecchi and Chiarini in Southern Abyssinia between 1876 and 1881.

To the *Bollettino* of the Italian Geographical Society for September, Count L. dal Verme sends an account of an excursion to the new crater, which made its appearance during the recent eruption of Mount Etna, and which has been named Monte Gemmellaro, in honour of the distinguished geologist of Catania. It lies 300 metres below Monte Nero, at an altitude of 1500 metres above sea level, and may now be approached without much risk from the side of Nicolosi, the route passing by the Convent of Monte S. Nicola (940 metres), and thence by Monte Gervasi and to the west of Albano Pinitello and other older but now quiescent cones. There is an alternative, but much more difficult and dangerous, route further east, running also from S. Nicola straight to the foot of Monte Albano, where the explorer must dismount, whereas by the longer road he may ascend beyond Ca' dei Cervi, close to the new crater, by a bridle-path easily accessible to mules. The cone appears to rise 140 metres above the old level, and has a diameter of about 200 with a depth of perhaps 40 metres, showing at the bottom two openings 3 or 4 metres wide, ejecting a little vapour at short intervals, accompanied by a slight rumbling noise. There was a third aperture with a diameter of some 10 metres, which emitted such a continuous stream of vapour that it was impossible to form any idea of its depth. During the eruption, Gemmellaro appears to have ejected about 66 000,000 cubic metres of eruptive matter, covering a space of 5½ square kilometres on the flank of the mountain, and approaching close to the village of Nicolosi (700 metres), near the upper limit of the vine. During the eruption, which lasted twelve days, the vineyards of this district were wasted to the extent of some 20,000*l.* ; but scarcely any other loss was suffered by the inhabitants, not one of whom perished from the all-devouring stream of molten lava.

The same number of the *Bollettino* has an instructive paper by S. Raineri, on the rise and development of submarine telegraphy from the first tentative experiments of Watson (1747) and Schilling (1812) to the last cable laid on the floor of the Atlantic between Valentia and New York. The historical labours and discoveries of West, Wheatstone, Newall, Brett, and other pioneers are briefly described, and a full account given of all the oceanic cables at present girdling the globe in all directions. The paper is accompanied by two comprehensive charts and tables containing the names, dates, and lengths of all the lines completed down to the year 1885.

From the Report of the Council of the Straits Branch of the Royal Asiatic Society for the past year, we learn that an entirely new map of the Malay Peninsula is now in course of preparation, and will shortly be sent to England for publication. Recent explorations in Pahang, and the work of surveyors in the service of the native States have added greatly to geographical knowledge during the last few years, so that it has been found possible to make great improvements in the map of the Peninsula published for the Society in 1879 by Mr. Stanford. The Council further suggest as a subject worthy of the attention of the Colonial Government and of the Society, the preparation of an authorised Statistical Gazetteer, to which residents, students, travellers, and men of science may turn for authentic information regarding the Straits Settlements and the native States of the Malay Peninsula. Such a work, the Council thinks, should embody a full account of these regions, their inhabitants and productions, in the departments of geography, geology, ethnology, religion, manners and customs, history, arts, manufactures, agriculture, commerce, zoology, ornithology, ichthyology, &c., and should give a concise account of every town and village of importance within these

limits. It would carry on in the Far East the work already performed in British India and Burmah.

A SPANISH Expedition under Capt. Cervera has been exploring Adrar in the Western Sahara. Capt. Cervera describes Port Rio de Oro, where he landed from the Spanish cruiser *Ligera*, as rather difficult of entry, but, once entered, as secure from all winds, with good anchoring ground, and from 10 to 30 metres' depth of water. "Rio de Oro" is a misnomer, as there is only one well of fresh water, and that very dirty. There are, however, good wells in the interior, and at four days' journey there is a running spring. The Expedition proceeded, between latitude 22° and 23°, south-eastwards 425 kilometres through an arid country of gneiss and granite, and struck the boundary of Adrar. The population is composed of four tribes—the Uled Delim, speaking and nearly all capable of writing pure Arabic, mixed with a few words of Berber origin. These tribes are nomadic, moving their tents from well to well for the pasture of their dromedaries, goats, and sheep. The capital of Adrar is Aatar, not Wadan, as hitherto believed. Wadan lies more to the south.

"HYBRID" WHEAT

IT is probably not generally known that the cereal from which we obtain our bread corn is almost invariably self-fertilised in nature, and that only a skilful expert can perform the delicate operation involved in the cross-breeding of wheat. The anthers, when near maturity, must be removed from a number of wheat-flowers, and on the following day the pollen of the male parent must be placed on the stigma. The opening of the glumes, however, is dependent on the swelling of the "lodicules," which only occurs when the temperature of the atmosphere is not less than about 75°. Below that minimum the florets will not open so as to expose the reproductive parts to the operator. The angle of opening of the glumes corresponds to this swelling, and when fertilisation has been performed the lodicules shrivel up and the glumes again close over the pistil. It had long been obvious that half a dozen different varieties of wheat, blossoming at the same time, may be grown in adjacent fields or in contiguous rows without the occurrence of interbreeding, in spite of the clouds of pollen which sunshine and warmth develop at the time of blossoming; and considering the remarkable results from the cross-fertilisation of numerous plants in gardens, it seems surprising that the same process should not have been applied to wheat. Many years ago a well-known selector and "improver" of cereals, the late Mr. Patrick Sheriff, tried some experiments in this direction. His usual method of improvement consisted in the selection and careful cultivation of "sports," and he was approaching the end of his career when his earliest attempts at cross-breeding were made. The increased vigour of wheat, the moulding of the ear, the production of a larger and fuller ear, with superior grain, earlier maturity, and the modification of the straw so as to render it stronger, or shorter, and less liable to become laid as in the present season, are all improvements which may certainly be accomplished in regard to this cereal, just as analogous modifications have beeen effected in animals and some other plants by the recognised methods of breeders.

The wheat-crop of the United States reaches at present 50,000,000 quarters, or four times that of England, and this may in some measure account for the numerous experiments in cross-breeding by scientific American farmers, and especially by some of the professors of agriculture in the colleges of that country. The same remark applies to France, where the cultivation of wheat is relatively far more important than in England, and where the noted seed-firm of Vilmorin are now in the midst of the work of cross-breeding. But even in England, disheartened as farmers may be as regards wheat-culture, their prospects might certainly be improved if the average production of this cereal could be increased, its quality improved, and its liability to disease and injury from indifferent weather diminished. Both growers and consumers, therefore, have an interest in the undertaking of Messrs. Carter and Co., the seedsmen, who for several years past have been engaged in the cross-breeding of wheat at their trial-grounds and gardens at Forest Hill. The collection of different sorts of wheat at this establishment includes varieties from every country which exports this grain to England. Some of them are not hardy, and the wretched appearance of the growing specimens of Persian and Indian varieties was probably due to their depreciation in our climate. Some of the colonial and other sorts were excellent, but none could compare to the so-called hybrids.

The operations commenced in 1882 by the sowing of a number of the best English and American varieties, and in the following summer twenty crosses were effected by experts who are usually employed by the firm in delicate manipulations of a similar kind in connection with garden vegetables and flowers. In the following autumn the hybrids, as they are usually called for convenience, were sown between the rows of the male and female parents for the sake of comparison, and in the succeeding year the mixture of the breeds became apparent. In one plot, for example, the female parent was a short-strawed velvet-chaffed variety, and the male a very large, bearded, and tall American wheat, and the offspring attained a stature exceeding that of the former by a foot, with smooth chaff, and stout thick-set ears bearing minute awns at the apex of the chaff of each grain. This last-named peculiarity, the occurrence of defensive points in serrated order from top to bottom of the ear, may be referred to as one of the many advantageous peculiarities which have been developed in the course of the experiments, and it has gained for the new variety the appropriate name of "Bird-proof."

Another of the cross-breeds, having the earliest of English varieties, Talavera, for one of its parents, was almost ready for cutting this year on July 21, when we inspected the new sorts, a very early date in the case of a late backward harvest. Another has the grains very firmly set, and therefore not liable to shell out even when the crop is dead ripe, as it usually is before the time of cutting in New Zealand, where this wheat will probably prove popular.

Another of the crosses proved to be a wheat with shorter straw than any other variety in cultivation, and this too will prove a valuable modification, since neither soil nor season, however productive of straw they might be in certain years, could throw the crop down. Now does it surprise the experts that the offspring of two parents which are both of average height, should prove to be a dwarf in regard to the length of its straw, since they have had occasion to observe the same thing in the breeding of peas—two sorts of peas, each 4 feet high, and requiring the support of sticks, having produced a very useful seedling of 2½ feet, which requires no such artificial assistance.

We cannot attempt a detailed description of the numerous other peculiarities—some of them promising to be highly advantageous—which have been developed in the course of these wholesale experiments. But we may here observe that the most tiresome part of the business has proved to be the fixing of the types after the crossing had been accomplished. The work, however, has proved sufficiently successful to encourage the experimenters to undertake the cross-breeding of barley as well as wheat, and to lead them to anticipate a large demand for their new varieties, not only in this country, but in the colonies.

H. E.

DR. AUGUST WEISMANN ON THE IMPORTANCE OF SEXUAL REPRODUCTION FOR THE THEORY OF SELECTION [1]

IN NATURE, vol. xxxiii. p. 154, was given an article on Prof. Weismann's most interesting and important memoir on "The Continuity of the Germ-Plasma considered as the Basis of a Theory of Heredity." The present memoir also abounds with interest, and may be regarded as following naturally from the former one as a continuation and further elaboration of some of the questions raised in it. The main aim of the memoir is to establish the position that the process of sexual reproduction is the prime agent by which all the varied differentiations of the complicated phyla of the Metazoa has been brought into existence. A strong part of the argument is devoted to the establishment of the position that peculiarities acquired by the parent are not transmitted to the offspring, and to showing that the hypothesis that such acquired peculiarities are transmitted is not necessary for the explanation of the known phenomena of heredity and the mode of origin of the series of organic forms. It will be remembered that the assumption of this position forms an important and necessary factor in the theory of the

[1] "Die Bedeutung der sexuellen Fortpflanzung für die Selektions Theorie." (Jena: G. Fischer, 1886.)

continuity of the germ-plasma, but it was one which in the former memoir was only lightly touched upon.

A large part of the contents of the present memoir was delivered as a lecture at a meeting of the German Naturalists' Association at Strasburg in September 1885; but numerous alterations and additions have been made, and six appendixes on special points have been added.

At the outset, special attention is drawn to the essential difference between "those special new characters which are correctly to be included under the term 'acquired,'" and the much broader class of new characters generally. Only those new characters can be termed "acquired" the origin of which is due to external influences, and not those which depend on the mysterious collaboration of the different tendencies of heredity which meet one another in the impregnated germ. These latter are not acquired, but "inherited." If, as the author holds, acquired characters are incapable of being transmitted to the progeny by the parent, then a much wider field of action must be ascribed to the processes of selection in the transformation of species than hitherto, since the modifying influences of external conditions being confined to the individual, can, in the vast majority of instances, have no effect on the transformation of species.

After discussing Nägeli's postulation of the existence in organisms of a special internal modifying force to account for the phenomena of adaptation, and showing that such a force has no existence at all, and that there are no reasons or justification for assuming it, the author dwells on the adequacy of the theory of selection to account for the facts. He insists specially on the necessity that the changes occurring during the transformation of a species, both in the organism itself and in the conditions of existence, shall take place by the smallest possible stages with the utmost slowness, so that at no moment of the entire process of transformation shall the species remain inadequately adapted to its conditions.

The possibility of the transmission of acquired characters being excluded, it is assumed that, in the case of all animals and plants which are reproduced by real germs, only those characters can be transmitted to a succeeding generation which were already present in the germ at the time of its formation.

On the theory of the continuity of the germ-plasma, a certain minimum of the active substance of the germ, the germ-plasma, always remains unchanged when the germ develops into the organism, and this remains of the germ-plasma becomes the basis from which the germ-cells of the new organism are formed. Thus there is a continuity of germ-plasma from one generation to another, and the impossibility of the transmission of acquired characters follows directly from this position, since the molecular structure of the germ-plasma is already determined within the embryo.

There are no facts which really prove that acquired characters can be inherited, although many attempts have been made to render such a supposition plausible. On the contrary, the evidence against it is abundant. The children of highly-civilised races of mankind, when brought up in isolation, show no trace of a language, and the results of experiments made on plants tell markedly on the same side.

Twenty-two pages of appendixes are devoted to demonstrating this most important position—the influence of which on future speculation with regard to organic evolution can hardly be over-estimated—that acquired peculiarities are not hereditarily transmissible. Only some of the statements with regard to the familiar instance of Brown-Séquard's hereditarily epileptic guinea-pigs can here be given.

Brown Séquard, as is well known, produced artificially epilepsy in guinea-pigs by means of section of certain parts of the central or even peripheral nervous system in the living healthy animals. The progeny of these guinea-pigs inherited the disease of the parents. The experiments were repeated by Obersteiner, and there is no doubt of the fact. Still, urges our author, this is not to be taken as a proof that acquired peculiarities can be inherited. Epilepsy is no morphological peculiarity, but a disease.

If there were found in the epileptic offspring a distinct and evident morphological alteration in the nervous structures caused by and corresponding with that produced by injury in the parent, and which was at the same time the cause of the epilepsy in the offspring, then the question of the actual transmission of an acquired morphological peculiarity might be justly raised.

That such is the case is, however, not only not proved, but very improbable. What is certain is that many of the young of such artificially epileptic parents are small and feeble, and often die early; others show deformities and sores on various parts of their bodies. In rare instances certain of these young exhibit epileptic symptoms. Two only out of thirty-two young of epileptic parents showed the symptoms, and these soon died, having but very little vitality.

The facts may be fairly expressed by stating that the guinea-pigs artificially rendered epileptic transmit to a part of their offspring the disposition to various diseases of the nerves, to diseases of the motor nerves, and in a less degree to those of sensory nerves, and most markedly to those of trophic nerves. In rare instances, those in which paralysis is most developed in the offspring, the epilepsy is also transmitted with it.

If the pathological change in the nervous structures which follows injury and produces the epilepsy be due, as is possible, to some as yet unknown microbe growing within its substance, it is far easier to understand the transmission of such a microbe from the parent to the offspring in the adult sperm-cell or ovi-cell than to conceive of the disease being communicated in the form of a molecular change in the germ-cell. That such a transference of a microbe in the ovi-cell or sperm-cell occurs in the case of syphilis and tuberculosis is probable, and it is certain that such does occur in the case of the muscardine silkworm disease. Such an explanation would account, in the case of the guinea-pigs, for the fact that the various offspring exhibit various forms of nerve diseases, which remains unexplained if it be assumed that this is a case in which there is an hereditary transmission of a morphological character, namely, a pathological change of structure of a nervous centre. The way in which the artificial epilepsy develops itself in the guinea-pigs after the operation, creeping gradually over the body, and ensuing in the same way after injury to the most varied parts of the nervous organs, is a proof of its infectious nature. The change produced by section of the nerves is obviously not the direct cause of the epilepsy, but only serves to originate a process of disease which is propagated centripetally, with the final result of the appearance of epileptic symptoms.

The germ-plasma is immensely complex in its finest structure, but it has a remarkable power of persistence, since it absorbs nourishment and grows enormously without in the least changing its complicated molecular structure in so doing. This follows from the fact that many species (*e.g.* the Egyptian ibis or the crocodile) have reproduced themselves for thousands of years without change. Further, since the quantity of germ-plasma contained in the single germ-cell must be regarded as extremely small, and as only a minute fraction of this remains unchanged when the germ-cell becomes developed into the new individual, the growth of this fraction in the individual must be a most enormous one, as usually thousands of germ-cells are produced by it.

Since the germ-plasma can remain unchanged in molecular structure in spite of such vast increase in bulk, it is obvious that it is not easily to be modified, and it is probable that the direct influence of modifications in surrounding conditions on the germ-plasma has no effect of any importance on the production of hereditary individual variations. These must have another origin, and this, according to Weismann, is to be sought in the mode of reproduction occurring amongst most organisms at present existing—sexual, or as Haeckel terms it, amphigonic reproduction. This consists, as is well known, in the fusion of two antithetic germ-cells, or possibly nuclei only, which contain the germ-plasma, which in virtue of its peculiar molecular structure, is the bearer of the heritable tendencies of the organism from which the germ-cell originates. Thus in amphigonic reproduction two different sets of hereditable tendencies are to a certain extent mingled with one another. It is this process of mingling which is the cause of the occurrence of hereditarily transmissible individual peculiarities, and it is the production of these peculiarities which it is the office of amphigonic reproduction to effect. Amphigonic reproduction supplies the material for the development of individual variation out of which selection produces new species.

This is a most startling conclusion, and directly opposed to almost all former views on the action of sexual reproduction. The amphigonic process has been regarded as having the effect of rapidly obliterating any deviations from the specific type which may arise in the members of a species. With regard to specific characteristics this may still hold true, since the deviations from them are of so rare occurrence that they are unable to hold their own against the great mass of normally-formed

individuals. But it is otherwise in the case of the minute differences which are characteristic of the individual, because every individual possesses them, and each in a different manner. Here a compensation of the differences could occur only if the entire species were composed of but few individuals, but the number of individuals which constitute a species is in most cases practically unlimited, and thus an intercrossing of all of these with all the others with the result of the compensation of the individual differences is impossible.

The process of amphigonic reproduction is able to bring about what is absolutely essential to the working of selection as an all-powerful agent in development, namely, the summing up of the small individual differences it has to deal with in the direction of the result aimed at, and the production by this means of new characters. Such summing up of minute characters is impossible in the case of species with non-sexual reproduction. In the course of successive sexual generations the differences between the individuals of a species must continually increase, not as regards the greater differences, but as regards the constantly new combinations of individual peculiarities which are formed. Imagine a number of individuals of a species distinguished each from the others by a few hereditable peculiarities; in the next generation no single individual could be like the others, they must all be different. Further, not one of the progeny could be identical with one of their parents, since each has combined in it the hereditable tendencies of two parents, its organism being as it were a compromise between the developmental tendencies of both. In the third generation the hereditary tendencies of two individuals of the second generation are combined. But since the germ-plasma is no longer simple, but is already compounded of two individual kinds of germ-plasma, an individual of the third generation will represent a compromise between four different hereditable tendencies. In the fourth generation eight such tendencies must be combined; in the fifth, sixteen; in the sixth, thirty-two. Each of these tendencies may show its effect more or less marked in this or that part of the organism as it is developed, and thus in the sixth generation a number of the most different combinations of the individual peculiarities of the ancestors may be exhibited; combinations such as never before existed in the history of the species, and such as never can occur again.

The prepotency of the various kinds of idioplasma which compose the germ-plasma of the germ-cells of each individual must vary in intensity at various periods of its life. This must be assumed in order to account for the fact that the several children of the same parents are never exactly alike. The presence of the small individual peculiarities postulated as displayed in the hypothetical series of individuals of the first generation is accounted for as having arisen, not amongst the higher organisms, the Metazoa, but amongst their unicellular Protozoan ancestors. Amongst these there is no distinction between body-cells and germ-cells; their reproduction is by division, and in this case every modification of the body of the organism, every individual peculiarity, however produced during the course of life, must be directly transmitted to the offspring. Here parent and child are in a certain sense still one and the same being. The child is a portion of the parent, and commonly half the parent. The conditions are entirely different from those occurring in the sexual reproduction of the Metazoa, by which acquired peculiarities are not transmitted.

Hereditarily transmissible variation having arisen in the Protozoa by the direct action of external causes, was retained by the Metazoa when they became developed; and as amphigonic sexual reproduction arose at the same time, the variation became thereby enhanced and increased in complication, and preserved in ever-changing combinations.

In the theory of sexual reproduction put forward by Prof. W. K. Brooks, of Baltimore, in 1883,[1] there is a resemblance to the views here maintained, in that sexual reproduction in it also is regarded as the means which is employed by Nature to produce variations, but the mode in which the influence is supposed to act is entirely different in the two theories, Brooks attributing the main effects in variation to the inheritance of acquired peculiarities, and to what may be termed the "circulation of the germ-plasma." His theory is a modification of Darwin's "pangenesis." He assumes, like Darwin, that each cell of the body of higher organisms throws off minute gemmules, not always and under all conditions, but only when they encounter unusual circumstances of existence. Whenever the normal functions of any component cell of the body are disturbed, "it throws off small particles which are the germs or gemmules of this particular cell." These gemmules are, according to Brooks, capable of passing to all parts of the body, and may pass into an ovarian ovum or a bud, but the male germ-cell has a special attractive force for them, gathering them within itself and storing them up. It is one of the peculiar merits of the theory of the continuity of the protoplasm that it dispenses with all necessity for any hypothesis of a circulation of gemmules or germ-plasma, so complicated and difficult to understand as these hypotheses are. As soon as the inheritance of acquired peculiarities is denied, such hypotheses are not required. Brooks further differs widely from Weismann in ascribing to the two germ-cells concerned in impregnation a different *rôle* in the process, the egg-cell or conservative principle being supposed to be charged with comparatively few gemmules, the sperm-cell, or radical principle, with many. This view, that the male germ-cell has a different part to play during the construction of the embryo from the female germ-cell is considered by Weismann to be untenable, because it is in contradiction with the simple matter of observation that human children on the whole are able to inherit just as many characteristics from the mother as from the father.

Apparently, the only function of amphigonic reproduction is the production of a supply of hereditable individual peculiarities on which selection may work, and as the development of the whole higher organic world depends on these processes, the part which amphigony has to play in Nature is one of the most stupendous conceivable, and hence its wide, almost universal, distribution in the animal and vegetable kingdoms. Nevertheless, it is not in any way contended that amphigonic reproduction originally came into existence in order to render the production of species possible. The process must have been already present before it evoked the hereditable variability, and its first appearance must therefore have had another cause. This cannot at present be explained with any certainty, but the key to the problem lies in the conjugation of the Protozoa, the predecessor of amphigonic generation. The fusion of two unicellular individuals into one, the simplest form of conjugation, must have a direct and immediate action which is of advantage to the existence of the species concerned. The view taken by Hensen and E. Van Beneden and others, that conjugation, as well as sexual reproduction generally, effects a rejuvenescence of the organism, is discussed and rejected as unsatisfactory. "The entire conception of rejuvenescence has something indefinite and nebulous about it. The assumption of the necessity of a rejuvenescence of life, brilliant as it is, is scarcely to be reconciled with our other conceptions of the nature of life based on purely physical and mechanical forces. How can it be conceived that an infusorian which has at last by repeated division exhausted its power of reproduction can recover this power by fusion with another similarly effete infusorian? Twice nothing does not make one, and if it be assumed that each infusorian retains half its reproductive force, the two combined would result only in one whole, but this could hardly be termed rejuvenescence. It amounts only to an addition such as, under other conditions, would be produced by simple growth."

It is best to assume in the present state of knowledge that living matter is endowed with a power of unlimited assimilation and consequently unlimited capability of reproduction, and that the form of reproduction, whether sexual or asexual, of itself exercises no influence on the duration of the process. It has not been proved that reproduction by division can never take place indefinitely. The phenomenon of parthenogenesis is strongly against the hypothesis of rejuvenescence, for, if impregnation represents a rejuvenescence, and essentially consists in a combination of energies and materials which in virtue of their differences give rise to the development of reproductive force, it is difficult to understand how occasionally the same reproductive force can be produced by one of the two materials, only the egg-cell. The common assumption that in the case of parthenogenesis a single impregnation suffices for a whole series of generations has no grounds of support, and is at variance with the fact that the same egg which may develop parthenogenetically (in the queen bee) is also capable of fertilisation.

The primitive action and meaning of conjugation may at present be best provisionally defined as a strengthening of the forces of the organism in relation with reproduction, which occurs when, on account of external causes, such as atmosphere, temperature, and want of food, the growth of the single animal to the size necessary

[1] W. K. Brooks, "The Law of Heredity: a Study of the Cause of Variation and the Origin of Living Organisms" (Baltimore, 1883).

for reproduction is not possible. This cannot be regarded as equivalent to rejuvenescence, since rejuvenescence is a process necessary for the maintenance of reproduction, and ought to occur periodically entirely independently of external conditions, whilst according to the above view conjugation originally only presented itself under unfavourable conditions of life and helped the species to surmount them.

Amongst the higher Protozoa the original import of conjugation seems already to have dropped into the background, as shown in the change in the nature of the process itself. The higher Infusoria are only temporarily fused with one another in conjugation, and it appears possible, and even probable, that the process has here already attained the full significance of sexual reproduction, and is to be regarded as functional as a source of variability only.

Amphigonic reproduction, having existed through countless generations of Protozoa in the form of conjugation, passed over to the Metazoa, and, though its original physiological effect lost importance or retired altogether into the background, was preserved from extinction and firmly retained because of the immeasurable advantages which are conferred by it in endowing the species with the power of adapting itself to new conditions of existence. The formation of new species which was possible amongst the lower Protozoa even without amphigony, amongst the Metazoa and Metaphyta was to be attained only by that process.

Amphigony has been lost in certain cases, either partially, as in the case of some lower Crustacea amongst which parthenogenetic generations alternate with sexual, or entirely, as in the case of certain gall-insects and plant-lice amongst which parthenogenesis has become the only form of reproduction. Such restriction to parthenogenetic reproduction may act so as to secure the existence of a species for a time, but according to the views as to the origin of hereditary variability here maintained, such a species dependent on parthenogenesis alone for reproduction must be near its period of dying out, as unable to adapt itself to any new conditions of existence which may arise, since in the loss of amphigonic reproduction it has lost the capability of mingling and increasing the individual hereditable peculiarities which occur amongst its members.

This conclusion is supported by the fact that no whole groups or genera occur the species of which are entirely parthenogenetic in their reproduction.

The persistence of functionless organs in species which are reproduced parthenogenetically is a further corroboration of the general view as to the import of amphigonic reproduction here maintained. Since acquired peculiarities are not inherited, organs which fall out of use cannot become vestiges in a direct way, as has been hitherto assumed to be the case. The functionless organ becomes indeed weaker and less fully developed in the individual which does not use it, but this reduction in the organ is not transmitted to the offspring.

The explanation of the undoubted fact that such organs do become vestiges must be sought elsewhere. In order that any particular part of the body in any species may be maintained at the height of its functions, all individuals which possess this part in less completely perfect development must be excluded from participation in the act of reproduction by perishing in the struggle for existence. As soon, however, as an organ ceases to be useful, this uninterrupted selection of the individuals with the best organs for the purpose of reproduction ceases also, and a condition arises which the author terms "panmixia." Now not only the individuals with the best organs participate in reproduction, but also those with inferior ones. A mixture of all kinds of gradations in goodness and badness in the organ must be the inevitable result, and thus in the course of time a universal deterioration in the organ must be produced. The remarkable fact that the gradual disappearance of functionless organs is extremely slow appears much more in keeping with the above views as to the nature of the process than with those hitherto adopted. The effect of disease of an organ in the course of a single life is a very well marked one, and if it were transmissible even to a reduced extent direct to the offspring, the organ must become reduced to a minimum even in a hundred generations. Yet how many million generations must have elapsed since the whalebone whale abandoned the use of its teeth?

If this new view of the cause of the reduction of disused organs is assumed as correct, it follows that vestiges of organs can occur only amongst species with amphigonic reproduction, not amongst those with parthenogenetic reproduction only, and this appears to be the case. Superfluous organs do not become rudimentary in species parthenogenetically reproduced. As far as the author's investigations extend, the receptaculum seminis does not become aborted in such species, although it is entirely without function. Thus in Chermes, which is without males, the receptaculum seminis is present in the females unchanged; whilst, on the other hand, in Aphis, another plant-louse in which amphigonic reproduction is not extinct, but alternates regularly with parthenogenesis, the receptaculum seminis has become lost in the summer female.

These evidences in favour of the general views here expressed form, of course, no absolute proof of their correctness, but only give evidence in favour of their probability. Further evidence cannot be offered at present, the phenomena dealt with being extremely complicated and their explanation being such as can only be approached gradually.

The author, however, considers that he has plainly shown that the selection theory is by no means incompatible with the conception of the "continuity of the germ-plasma," and further, that as soon as this conception is accepted as correct sexual reproduction appears in an entirely new light, displays a reason for its existence, and becomes to a certain extent comprehensible.

H. N. MOSELEY

N.B. A criticism of Prof. Weismann's above theories by Prof. von Kolliker appears in the *Zeitschrift für Wissenschaftliche Zoologie*, in the October part just issued.

THE FUNCTION OF A UNIVERSITY[1]

I GRATEFULLY accept the honour with which I have been invested thus publicly, and with such kindly feeling. In the future, as in the past, I shall give you my best endeavours.

By a fortunate accident it has happened that I am not called upon to speak to you on behalf of the University of California before I know somewhat of it. The six months which have elapsed since I entered upon the duties of the high office which I now hold, I have utilised in studying with minute care the University in its main features and in some of its details. This is not the place nor the time to speak of minor matters. It is, however, the very place and the very time for me to say to this audience that no friend of the University has any cause to fear, so long as all of us, Regents, Professors, and students alike, remain united in the future, as we are at this present moment, in a single effort toward the same high ends.

For nearly a hundred years the American Republic lived, and grew, and prospered, and the community of nations hardly knew her, and barely gave her place. So, on a smaller scale, it has been in California. The University here has lived, and grown, and prospered, and the communities outside of our own small circle hardly know us, and grant us our place reluctantly. It is a perfectly safe prediction that within the next twenty years, possibly within the next ten, the State of California will find suddenly that here in her midst she has a force on which she never reckoned—a reserve on which she never counted.

It is easy to see what advantages would come if this conviction were now wide-spread and firmly held. It is easy to seek feverishly to make ourselves quickly known, in order that we may be more widely useful. But, I am more and more convinced that if we are always ready, like a strong man, our opportunity will be here almost before we realise it.

Vital Points and Fundamental Principles.—What, then, are the aims upon which our eyes must be ever fixed, and toward which our energies must be ever directed? I will not name them all, nor count them over one by one. But I think that I can point out certain vital points that must be guarded; certain principles that must be fundamental. Let us consider the demands which the community makes of the University, and again, the standards which the University should set for its individual members.

In the first place we must carefully examine what it is that we, as citizens, demand from the University. We must see to it that what we demand is consonant with what we ought to demand. If we find that we disagree with what seems to us to be the position of the University, ought we not in fairness to calmly inquire which of the two is right? Is there not at least a certain presumption that the efforts of a body of intelligent scholars cannot be all misdirected? The usual and careless way of meeting this question, even on the part of those who count

[1] Inaugural Address by President Holden at the University of California.

themselves firm friends of the University, is to pass over these differences of opinion lightly, and to lay them to the errors of the intelligent scholars themselves. "What does a college professor know about life?" we say; "he knows his speciality, his mathematics, his political economy, his physics. Let him keep to that and we are satisfied. But let us, who are engaged in the practical business of life, judge of life and its needs."

We, the faculties of the University, might admit this provisionally and for the sake of peace, and inside our web here at Berkeley go on spinning our theories and trusting to their truth for their commanding influence in the future of the State. We will do that most certainly, and if the theories are right they will prevail. If they are wrong we shall be brought to confusion.

The University Useful and Practical.—But we claim more than this. We claim that the University is one of the most useful, and in a high sense practical parts of the machinery of the State. It has a function as important, or more important than any other. It shares this function with the Church, and the voices of both are to be your guide. The chief and highest function of the University is to assert and perpetually prove to you that general principles—laws—govern man, society, nature, life, and to make unending war on the reign of temporary expedients.

Think how fundamental is this use of the University. Think in how many ways we accomplish it. In the lecture-room, in the laboratories, in the machine-shop, we bring the student face to face with history, with nature, with fixed qualities. In history, in philosophy, in politics, in physics, we see that definite causes produce their definite and inevitable results. In the laboratories we find that nature, candidly interrogated, gives unambiguous answers; that mathematical prediction,—the modern prophecy—is inevitably fulfilled in experiment. In the machine-shop we learn that the hard results in brass and iron will not lie, but that they point relentlessly to careless, shiftless errors, if they exist, or testify to faithful, honest, laborious work if it has been done.

General Principles against Temporary Expedients.—There is no day and there is no hour of the student's life that he is not brought face to face with results, and taught to see that these flow from principles of universal application. Just in so far as a teacher can bring forth this great truth is he a successful teacher. Just in so far as a graduate has learned it, is the work of the University priceless to him. Just in so far as our professors and our students alike go forth into society and proclaim and prove the unending reign of general principles and the utter folly of putting temporary expedients in their place, is the University of prime value and use to the State. There was never a period or a country in which the reign of fundamental law needed more constant assertion and more perpetual proof than in our own period and our own country. All our modern inventions which give quick locomotion and quick transmission of thought tend to exalt the temporary expedient and to debase the general principle. The merchant of old time sent his ships to the Indies with their orders for two years or more; the diplomatist in a foreign country was separated by weeks or months from instructions by the Foreign Office. Now it requires but an hour to reach the uttermost parts of the earth. We have cable despatches which recount the doings of the King of Dahomey. The merchant changes his orders in Bombay as he reads the morning paper; the Secretary of State arranges the affairs of Tuesday on the afternoon of Monday.

The immediate and harmless effect of all this is to paralyse continuous effort based on sound belief, and to substitute a wavering policy of daily temporising. But the living danger is that society may come to permanently distrust the reign of laws. Recollect that we have to train our young men to appreciate this vital truth in the midst of a society where there are apparently many glaring exceptions to the rule; in a society where wealth has come, it seems by accident, and where power seems not to have been gained by work. And when you remember this, remember also how deep and profound your gratitude should be to any institution which is by its traditions and its very nature devoted to the incessant announcement and to the perpetual proof of the fundamental truth of all life here and hereafter, namely, that it is governed by unchanging principles which cannot be evaded nor shirked, and that a national or a personal life built on the expedients of the day, like a house built on the sand, will inevitably come to ruin. When this truth is grasped and firmly builded into the character, then it is that the steam-engine and the telegraph and all the myriad inventions of the day first become truly useful. The man who can command them aright has his powers doubled and trebled. It is the highest use of the University to train such men.

President Gilman's Test of a University.—You must not for one moment forget that the power of a university lies in its *men*. In its governors, its professors, and in its students. If you come here to our beautiful grounds and see them fair as they are today and always, if you see fine buildings and many of them, if you find our laboratories stocked with costly apparatus and our libraries with splendid books, you must not for that reason suppose you have a university fitted to the needs of the State. You are to inquire about far other things. And it is of prime importance that every citizen should know exactly what questions to ask. Nowhere have these questions been more eloquently or more pregnantly put than in a splendid address recently delivered by our former President, Dr. Gilman, at the noble University over which he now presides: "Remembering that a university is the best organisation for the liberal education of individuals and the best organisation for the advancement of science, apply the double test—what is done for personal instruction, and what is done for the promotion of knowledge?—and you will be able to judge any institution which assumes this name.

"Ask, first, is it a place of sound education? Are the youth who are trained within its walls honest lovers of the truth? Are they learned, are they ready, are they trustworthy? When they leave the academic classes do they soon find a demand for their services? Do they rise in professional life? Are they sought for as teachers? Do they show aptitude for mercantile, administrative, or editorial life? Do they acquit themselves with credit in the public service? Do the books they write find publishers? Do they win repute among those who have added to the sum of human knowledge? Have they the power of enjoying literature, music, art? Can they apply the lessons of history to the problems of our day? Are they always eager to enlarge their knowledge? Do they become *conservative* members of society, seeking for progress by steady improvements rather than by the powers of destruction and death? Are they useful, courteous, co-operative citizens in all the relations of life? Do the charities, the churches, the schools, the public affairs of the community receive their constant consideration? Are there frequent manifestations among them of unusual ability in science, in literature, in oratory, in administration? As the roll of the alumni increases, and the graduates are counted by hundreds and not by scores, does it appear that a large proportion are men of honourable, faithful, learned, and public-spirited character? These are the questions by which, as the years go on, a university is to be tested; or, to sum up all questions in one, Is it proved to be a place for the development of manliness?"

It is to be noticed that the stress is laid upon one chief thing—manliness—and that two main questions are to be asked. What does the University do for personal instruction? and what does it do for the promotion of knowledge?

The answers to these questions will depend in every case upon the men whom the University has chosen as its teachers. It will depend not only on their intellectual attainments, but upon their personal characters. It is a most fortunate thing that the following out of a life of true devotion to learning brings, in so vast a majority of cases, the excellences and beauties of character which we desire and look for. We can all point to eminent examples of this in our midst—and it is so everywhere. We should see in a true University the true spirit of research kept alive and eagerly active. How can you teach a young and ardent mind by means of examples culled from books alone? The vast panorama of nature lies before us, glorious by day, resplendent by night, and it is only from the actual pursuit of knowledge at first hand from nature itself that true teaching power is to be derived. Mere information can be gained from books and libraries. True knowledge must be attained by studies that develop mind and character at once.

The Genuine Issues of Life.—How, then, are we, the faculties of this University, to send forth from our midst men and women who are genuine, true, high, noble, sincere, simple? Men and women whose natures are such, and whose training has developed, harmonised and rounded out their natures? We must be constantly on the watch to put the genuine issues of life before ourselves and before our pupils. We are constantly tempted to put the name for the thing. How hard it is to avoid this even in our personal conduct, and how doubly hard it is in

our public acts to point always to the essence, and not to indicate the accidents. We, all of us, suffer from the complexity of modern life which presents masses of detail, demanding attention, and distracting our imaginations with what seems to be but "a multitude of single instances." We lose the thread of logic and law and only grasp the tangled skein of various issues. We are prone to class quickly a man, an action, a belief, and have done with it and him. It seems to save our time. In reality it dissipates and degrades our life. Let u take a familiar example. We meet a man for the first time. Our friend classifies him for us. He is introduced to us as a man of affairs, a physician, or a lawyer. We accept the crude classification based on what he *does*, and we forget the divine possibilities of what he *is* or may be. We indolently accept a commercial classification and omit the reckoning with all the unknown possibilities within a human being. We do him an injustice, and we go on to dull our own minds and souls by repeated iterations of this stupid act until we become puppets meeting our like and not men meeting with our fellow-men. It is a lazy and a shiftless way, and unworthy of all of us. It inevitably dulls the mind by putting a word before a thought, a phrase before a principle, and this process ceaselessly repeated gradually eliminates all thought, and living men become mere dead automata in each other's eyes. Hardly any man is so dull that there are not possibilities unknown to you within him. To classify him at a glance and by a phrase is to deny the divine spark in him and a perceptive sense in your own heart. It is true that the higher a man's profession is the nearer should his life approach to the type signified by the name of that profession. It is safer to think you know somewhat of a poet when you hear that he is such than to predict the quality of a physician from his degree of doctor.

Complete Human Beings.—The University has no higher ideal than to train its students so that their practice may agree with their professions. But their complete professions are by no means signified by the formal degrees with which we invest them.

We grant the degree of A.B. to successful candidates. But A.B. does not really stand for what we have tried to teach. What we wish to teach our students and ourselves is to be complete human beings. Nothing *less* than this. There *can* be nothing more. We wish them to be H.B.'s first—human beings—and A.B.'s afterwards. Let any one of us try to see what is meant by a deserved title such as this. What *is* a human being complete in every way? Is there a manly virtue, is there a feminine grace, is there a divine aspiration which we can conceive to be lacking to such a personality? How carelessly we use the phrase, and with what debased significance! Is the man who has sacrificed his very nature to the service of money deserving of the title? Is it any better if power be the thing he has sold his birthright for? or vanity? or pleasure? or fame?

The moment we reflect upon the inner senses and upon the connoted meaning of the word, we see how we have debased it. We are used to lift a beggar from the ditch and to say with a pity that is half repulsion—at least he is a human being. But when we reflect we see that we can give no higher praise than this to the men who are the chiefest glories of the race. Think of David, King of Israel. How can we praise him, appreciate him, feel his power over us at this day, better than to recognise that he was a complete being human in every part? That is allied directly with Divinity. St. Peter, Socrates, the great Emperor Marcus Aurelius—these touch us through a chord of complete unison of their human natures with ours. What is it that is common to the great Alfred of England and to the poet who sang the beauties of the daisy overturned by the plough? What but this human nature that embraces our own and harmonises with its every part?

In America, young as we are, we have had our complete human beings. We can point to the oration at Gettysberg and know that the man who wrote it did so out of the fulness of a complete human nature. The soldier whose forces were overcome on that fearful field will live in history by his martial deeds, but he will be cherished in our hearts for the rounded symmetry of his humanity. In fiction we have all given this high degree. Where can we find more perfect examples than Col. Newcome or Henry Esmond? Is it not worth reflection to see *why* it is that these stand for us as types of what a man can become?

I think we can conceive of what our ideal of a human being should be by seeking to find the common quality of men so removed from each other in character and circumstance as King David, Peter the Apostle, Socrates, Alfred, Burns, Lincoln, Lee. The great Marcus has even defined such a man for us in formal words: he is "a man who delays not to be among the best, like a priest and minister of the gods; who uses the deity planted within him, which makes him uncontaminated by pleasure, unharmed by pain, untouched by insult, a fighter in the noblest fight, not overpowered by any passion, deep-dyed with justice, and accepting with his soul all that happens and is his portion."

It must be our aim and end to fix clearly in the mind of every pupil that the whole object of his college course should be one and the same as the whole object of his entire life, namely, to be a real human being. Not to strive for partial knowledge, for partial facts as an end, and finally to be graduated a Bachelor of Arts, but to strive for complete and utter manhood and to add to its magnificent qualities all the learning which our schools afford simply as a help towards carrying out his inmost and his highest aspirations. Each one of us should be ever striving to deserve among our fellows and in our most secret life this chief of all titles. The one that expresses the sum of all achievement possible to us; since when it is attained it fixes us as wholly human, and thus made in the image of divinity. The best title of our Master was the Son of Man, and He descended to this to show the term to which we might attain.

A Word to the Graduates.—And now, members of the graduating class, I wish to say one parting word especially to you, who are soon to see the formal signs of the approval of your professors and of our governors—the Regents.

In the name of the University I welcome you to your new estate. If we have done our duty by you, you are equipped for the beginning of your maturer life. If you do your duty by yourselves and by society there is nothing which you need fear to undertake. Here, on the very borders of the most western sea, in a golden land of promise, let me repeat to you the noble words which were first written down eighteen hundred years ago, in the midst of a savage wilderness, in the presence of hostile barbarians, by the hand of the greatest and most virtuous of the rulers of imperial Rome, sitting alone and silent in his soldier's tent. Let these great sentences be at once our farewell and our God-speed to each one of you:—

"If thou workest at that which is before thee, following right, reason calmly, vigorously, allowing nothing to distract thee, but keeping thy divine part pure, although bound to give it back immediately—if thou holdest to this, expecting nothing and fearing nothing, with heroic truth in every word and sound which thou utterest, then thou wilt live happy—and there is no man able to prevent thee."

ANTARCTIC EXPLORATION[1]

THE author began by referring to the results established by Gauss in 1839. Gauss proved: "(1) That the knowledge of Y (the west component of the horizontal component of terrestrial magnetism, called usually X) over the whole earth, along with the knowledge of H (the north component of H) at all points on a line running from one pole to the other, is sufficient for the foundation of a *complete* theory of the magnetism of the earth. (2) That a finally complete theory was also deducible from the simple knowledge of Z (the component of the earth's magnetism, that is directed to the earth's centre) on the whole earth's surface." There existed, for a large part of the earth's surface, data for large charts of the normal values of the declination of H and of Z, at the epoch 1880, from which X, Y, and Z could readily be deduced. These charts were accurate for the zone lying between 60° N. and 50° S. lat. (except for some parts of North Asia and of Central Africa); they were less accurate for 60° to 70° N. lat., and 50° to 60° S. Beyond these limits in the south, lay regions almost unvisited since Ross's Expedition in 1840-43; so that the charts were correspondingly weak in those latitudes. The charts show that the *Challenger* crossed the Antarctic Circle about the meridian 79° E. These and other somewhat recent observations made between 50° and 60° S. lat., show that considerable changes in the magnetic elements have occurred since Ross's time, and therefore the charts for 1880 cannot be com-

[1] "On the Advantages to the Science of Terrestrial Magnetism to be obtained from an Expedition to the Region within the Antarctic Circle." Abstract of a paper read at the Birmingham meeting of the British Association by Capt. Ettrick W. Creak, R.N., F.R.S.

pleted, especially as our knowledge of the changes is too limited to permit of the use of Ross's observations. Further it is desirable to have actual verification of Gauss's extension by theory of the magnetic elements at places where they are known to places where they are unknown. The position of the south magnetic pole is still undetermined, and magnetic observations are wanted from 40° S. to the geographical pole. For the carrying out of these views, Melbourne Observatory, being furnished with the necessary instruments, would serve admirably as a base station, with subsidiary bases at the Cape, and at Sandy Point, Magellan Strait, for the use of portable absolute instruments. Much of the survey could be done on board ship at sea, observations having now become so trustworthy by the process of "swinging ship." Portable instruments could also be used on *ice*, where their readings would be specially free from sources of error. The great effect of the ship's iron in high latitudes can be got rid of by experience, as proved in the voyage of the *Challenger*, an important matter being a proper position on board far the instruments. This position could be chosen immediately after the selection of the ship. The error in the vertical component varies with the "heel" of the ship; the horizontal error can be eliminated by the process of "swinging."

NOTES FROM THE OTAGO UNIVERSITY MUSEUM

VIII.—*On the Claspers of Callorhynchus*

IN my friend Mr. Patrick Geddes' able article, "Reproduction," published in the recently issued twentieth volume of the "Encyclopædia Britannica" (ninth edition), the following note occurs (p. 410):—

"In the curious Holocephalous fish, *Callorhynchus*, Jeffery Parker has recently adduced arguments for regarding the claspers as the surviving rudiments of a third pair of limbs."

As this passage was written under the mistaken impression that a somewhat wild theory, hither only communicated privately to one or two friends, had been published, I think it will be advisable to state exactly the grounds on which I am disposed, provisionally, to consider the Holocephali as the only existing hexapodous vertebrates.

In the Elasmobranchii (Plagiostomi) the male is well known to possess a single pair of so-called claspers, each having the form of a plate rolled longitudinally upon itself so as to produce an incomplete tube, and supported by a more or less complicated cartilaginous skeleton continuous with the basipterygial cartilages of the pelvic fin.

In *Callorhynchus*, on the other hand—and I believe the same applies to *Chimæra*, of which I have no specimen—the male has two pairs of organs, which may be called respectively the anterior and the posterior claspers. The posterior claspers are evidently homologous with the claspers of the Elasmobranchs: they occur in the same position, have the form of a plate rolled longitudinally into a tube, and are supported by a prolongation of the basipterygium. No doubt, like the corresponding organs in sharks and rays, they have an intromittent function.

The structures I call anterior claspers are situated a short distance cephalad of the vent, inclosed, in the position of repose, in a pouch of skin having a somewhat contracted slit-like aperture, so that the clasper is ordinarily hidden from view. The aperture of the sac is erroneously marked "peritoneal aperture" in Günther's figure of *Chimæra colliei* ("Study of Fishes," p. 184). In connection with the sac is a gland secreting a lubricating fluid, and closely resembling the well-known gland of the Elasmobranch clasper.

In the female, although the clasper itself is absent, a small glandular sac occurs in the corresponding position.

The anterior clasper itself is a somewhat complicated organ, consisting of three chief parts supported by cartilage. The largest of these, which forms the main support of the whole structure, is a strong irregular cartilaginous plate, articulated by an elongated surface with the anterior border of the pubic portion of the pelvic girdle in such a way that when in its ordinary position of retraction, the whole apparatus is folded back in the hollow furnished by the outer surface of the pubic cartilage. To this principal cartilage of the anterior clasper are attached two others: one a thin delicate plate, shaped like the human external ear, the use of which is not obvious; the other a somewhat thicker plate, rolled upon itself to form a tube, in much the same way as the posterior clasper, and evidently serving as a duct for the passage of the above-mentioned secretion. The whole apparatus is covered with soft mucous membrane, except the free portion of the principal cartilage which is studded with minute sharp denticles.

The clasper is exserted by the action of a strong muscle arising from the inner face of the pubic cartilage and passing over its anterior border to be inserted into the principal cartilage of the clasper. The plane of movement of the organ is nearly horizontal.

That a serial homology (homoplasy) exists between the anterior and the posterior claspers is suggested by the following facts:—(*a*) The general similarity of their structure; (*b*) they both articulate, mediately or immediately, with the pelvic cartilage; (*c*) they both lie in the line of Balfour's lateral ridge, *i.e.* of the hypothetical lateral fin; (*d*) the blood from both appears to be poured into a vein which is clearly the representative of the lateral vein of Elasmobranchii, which latter I have adduced reasons for considering as the vein of the proto-vertebrate lateral fin (*Trans. N.Z.Inst.*, vol. xiii. p. 413, and vol. xv. p. 222; *Proc. Roy. Soc.*, June 1886).

I regret that all my efforts to obtain earlier embryos of *Callorhynchus* than those I described three years ago in NATURE (vol. xxix. p. 46) have failed. It must therefore remain for future investigations to decide whether the anterior clasper of Holocephali is developed from a portion of the lateral ridge which usually atrophies, and whether its skeleton is formed by the concrescence of pterygiophores (radial fin-cartilages).

At present, therefore, the hypothesis that the anterior claspers of the Holocephali represent a middle pair of limbs is nothing more than a deduction from an unproved theory. I should not have ventured to publish it without further evidence if my friend had not, quite inadvertently, forced my hand.

Dunedin, N.Z., August 16 T. JEFFERY PARKER

SOCIETIES AND ACADEMIES

SYDNEY

Linnean Society of New South Wales, July 28.—Prof. W. J. Stephens, M.A., F.G.S., President, in the chair.—The following papers were read:—On some new or rare fishes from the Australian region, by E. P. Ramsay, F.R.S.E., and J. Douglas-Ogilby. A few notes are given on the curious Blennoid genus *Xiphasia* of Swainson, and a description is given of a species—*Xiphasia setifer*, Swainson—now for the first time taken in Australian waters. *Arrhamphus sclerolepis* and *Gastrotokeus biaculeatus* are recorded as fishes not previously seen on the New South Wales coast.—Catalogue of the Australian Coleoptera, part 5, by George Masters. The present part contains the large family of the Curculionidæ, numbering over 1200 species, and bringing the total number now catalogued up to 5625. It was stated that probably two more parts would complete the order Coleoptera.—Miscellanea Entomologica, No. 2: the genus *Liparetrus*, by William Macleay, F.L.S. This is a complete monograph of the genus *Liparetrus*. All the old species are redescribed, many new ones added, and the genus is subdivided into several sections and sub-sections. Altogether about 100 species are characterised.—Revision of the Australian Lepidoptera, No. 1, by E. Meyrick, B.A., F.E.S. Five families of the Macro-Lepidoptera, or Lesiadæ, Arctiadæ, Hypsidæ, Syntomididæ, and Zygænidæ, are monographed, numbering about 150 species, about half that number being new to science.—Notes on synonymy of Australian Micro-Lepidoptera, by E. Meyrick, B.A., F.E.S. The synonymy of fifteen species of Micro-Lepidoptera is corrected, from an examination of specimens in the British Museum.

PARIS

Academy of Sciences, October 18.—M. Jurien de la Gravière, President, in the chair.—A theory of the unequal flow of gases, by M. Haton de la Goupillière. Although geometricians have already solved a few questions relating to the unequal movement of fluids, no general theory appears to have yet been applied to the subject so far as regards the gases. The object of the present paper is to make good this want, and to present a complete solution of the problem in connection with the receptacles of compressed air for locomotives or tramways filled from reservoirs maintained by the compressing engines at a constant tension.—Researches on the tension of the dry bicarbonate of ammonia, by MM. Berthelot and André. The authors here discuss the important and complex problem, whether the tension of ammonia in the air, the ground, and natural waters, and its movements between these various mediums, is to be assimilated

to the tension of this free alkali dissolved in pure water and to its diffusion between an inert atmosphere and purely aqueous solutions. Numerous experiments here described show that the function of the three constituents of sal ammoniac is not the same in its dissociation, the carbonic and ammoniac gases, even in great excess, possessing no perceptible influence on the tension of the bicarbonate at the ordinary temperature, while liquid water determines its decomposition independently of the laws of dissociation of the salt.—On the origin of the motor nerves in the palate of the dog, by M. Vulpian. His experiments on the origin of the secreting nerves of the salivary glands and of the chord of the tympanum have led the author to the study of this subject, his conclusions mainly confirming the results already obtained by M. Chauveau, who operated on the horse and the ass.—Experimental researches on the cause of *rigor mortis*, by M. Brown-Séquard. In continuation of his previous paper (see last week's NATURE, p. 612), the author describes certain experiments, which seem to show that this phenomenon mainly depends on a contraction, that is, a muscular vital act beginning or continuing after the general extinction of life. At the same time it is not denied that a coagulation of the albuminous substances may also to some extent contribute to the rigidity which sets in immediately after death.—The mountain plants of the Parisian flora, by M. Chatin. It is shown that associated with the ordinary vegetation of the Paris district are found numerous highland and even Alpine specimens, such as *Swertia perennis*, *Atropa Belladonna*, *Euphrasia lutea*, *Digitalis lutea*, *Veronica montana*, &c., most of which are largely represented in the Alps and Scandinavia, and some few in the south of France. They generally flourish in localities where the conditions of life approach nearest to those presented by the Alps; but whether they are due to migration from those regions or are indigenous is a question reserved for future discussion.—Analysis of some cosmic dust which fell on the Cordilleras near San Fernando, Chili, by M. A. E. Nordenskjöld. This specimen, received last February from M. Stolp, of San Fernando, and weighing about 2 grammes, yielded on analysis: oxide of iron 74·59, oxide of nickel 6·01, silicic acid 7·57, magnesia 3·88, alumina 2·90, and minute quantities of lime, phosphoric and sulphuric acid, with traces of oxide of copper. This analysis shows that it is not a product of the Krakatão eruption, but comes for the most part from the inter-planetary spaces.—On surfaces inclosing cones of the second degree, by M. E. Blutel. The case is considered in which each cone touches its inclosure following a moving circle.—On the determination of the coefficients of expansion by means of the pendulum, by M. Ch. Ed. Guillaume. It is shown that this method, recently proposed by M. Robert Weber, cannot possibly yield the accurate determinations anticipated by him. All the apparatus needed for its application render the process extremely complicated, while under the most favourable conditions its precision will never exceed 1/300.—Theoretical value of the local attraction at Nice, by M. Hatt. Theoretic researches undertaken for the purpose of determining this value have led to the results here communicated, including some data tending to correct the geodetic latitude of Nice.—On some pyridic bases, by M. A. Ladenburg. Having two years ago determined the methods of synthesis for the pyridic and piperidic bases, the author has since succeeded, with the aid of MM. Roth, Lange, and Hesekiel, in preparing a whole series of these bases, which are here described.—Researches on the evolution of the embryo of the fowl, when the eggs are submitted to incubation in the vertical position, by M. M. Dareste. Of sixteen eggs treated in this way, only one was successfully hatched, all the other embryos perishing at various dates and under diverse conditions.—On the relations of the Leptocephalidæ to the conger-eel, by M. Yves Delage. Observations recently made at the Laboratory of Roscoff show that the Leptocephals, contrary to the opinion of Günther, are normal larvæ capable of transformation.—Contribution to the study of the Tertiary flora of the west of France and of Dalmatia, by M. Louis Crié. It results from this comparative study that five identical species and seven or eight closely-related types connect in a common palæophytic epoch the Tertiary districts of Mans and Angers in France with that of Monte Promina in Dalmatia.—On the discovery of a grave dating from the polished Stone Age, recently discovered near Crécy-sur-Morin, by M. A. Thieullen. The excavations carried out at this spot revealed two contiguous chambers built under a rock, and containing the skeletons of about thirty human beings of all ages and sexes, besides stone hatchets, knives, scrapers, and other relics of the Neolithic period, but no traces of pottery or the metals. The human remains are remarkably well preserved, five or six of the skulls being almost intact, and by their form apparently indicating the presence of two distinct prehistoric races.—On a meteorite found in a block of Tertiary lignite from Wolfsegg, by M. Gurlt, with remarks by M. Daubrée. This rare specimen of a meteorite, traced to Tertiary times, forms a mass of cosmic iron combined with some carbon and nickel, weighing altogether 785 grammes.—On the constant presence of micro organisms in the thermal waters of Luchon (64° C.), and on their action on the production of baregine, by MM. A. Certes and Garrigou. The object of this paper is to determine the presence of living organisms in thermal waters of the highest temperatures, to ascertain their nature and the part played by them in the production of the baregine or glairine commonly found in sulphurous waters.—On melanosis, a disease of the vine, by MM. Pierre Viala and L. Ravaz. This is described as a malady of American origin, not very injurious to French vineyards, and due probably to a parasitic fungus identical with the *Septoria ampelina* described by Berkeley and Curtis.

BOOKS AND PAMPHLETS RECEIVED

"The Functions of the Brain," new edition, by Dr. D. Ferrier (Smith, Elder, and Co.)—"Journal of Royal Microscopical Society," October (Williams and Norgate).—"Experimental Chemistry," new edition, by C. W. Heaton (Bell and Sons).—"Origin of Languages," by H. Hale (Cambridge, Mass.).—"Concerning Force, Impulsion, and Energy," by J. O'Toole (Hodges, Dublin).—"On the Temperature and the Rainfall of the Croydon District, 1881-85," by H. S. Eaton.—"The Mechanism of Nature," by A. M. Stapley (Cornish, Manchester).—"Bibliotheca Historico-Naturalis et Mathematica: Lager Catalog" (Friedländer, Berlin).—"Notes from the Leyden Museum," vol. viii., No. 4, October, by Dr. F. A. Jentink (Brill, Leyden).—"Natural History," by Dr. H. A. Nicholson (Chambers).—"Diseases of Tropical Climates," by Dr. W. C. Maclean (Macmillan).—"Proceedings of the Royal Society of Edinburgh," Session 1885-86, No. 121.—"Carte Géologique Générale de la Russie d'Europe," Feuille 139.—"Bulletins du Comité Géologique St. Pétersbourg," Nos. 7 and 8, 1886.

CONTENTS
